The earlier the tick is removed in the course of the illness, the more promptly the signs and symptoms will resolve. Forceps, not fingers, should be used to remove the tick. The tick's head should be gently but

firmly grasped, and slow, reverse traction should be applied to remove all body parts. Recovery generally is complete within 1 to 5 days. In one reported case, weakness did not resolve for several months.²⁶ Intensive supportive care is required if the patient has cranial nerve dysfunction. Ineffective ventilation and ensuing respiratory failure require assisted ventilation.

Myiasis

Myiasis is the invasion of a host's tissues by the larval stage (maggot) of nonbiting flies. Because of the immaturity of maggots, differentiating the various species is difficult. Myiasis can be classified according to the anatomic site of infestation (i.e., aural myiasis, ophthalmomyiasis, or cutaneous myiasis) or on the basis of the clinical syndrome (i.e., furuncular cutaneous myiasis, migratory cutaneous myiasis, or wound myiasis).⁶⁵ In the past, parasitic diseases were limited to their endemic areas. However, with the relative ease of worldwide travel, they are appearing with increasing frequency in the United States and other developed countries.⁴⁰

Etiology

The true flies of the order *Diptera* undergo metamorphosis in four stages: egg, larva, pupa, and adult. To different degrees, some larvae of the suborder Cyclorrhapha have adapted to a parasitic relationship with humans. Some are classified as obligate, facultative, or accidental parasites in humans. In each case, the larval stage of the fly is able to invade the tissues of the host and progress in the stages of metamorphosis.

Epidemiology

The occurrence of human myiasis has been linked to humid and warm climates that favor the breeding of flies. Epizootics in livestock, marginal housing, poor disposal of refuse, and undernutrition also are important factors in the development of human myiasis.⁵² In the United States, myiasis has been reported both from flies native to North America and from the larvae of flies acquired during foreign travel. More than 50 species of flies have been reported to cause human myiasis.

Pathogenesis

The pathogenesis of human myiasis differs with the degree of parasitic adaptation by each fly. *Dermatobia hominis* (the human botfly) uses a bloodsucking insect as a vector to deposit its eggs on a warm-blooded host. The larvae emerge from the eggs and then penetrate the host's skin, frequently using the puncture site of the carrier insect. The larvae develop within the dermal layer of skin, which leads to a boil-like swelling. During this period, the human host develops clinical symptoms. *D. hominis* and *Cochliomyia hominivorax*, the primary screwworm, are examples causing obligate myiasis.⁵² *C. hominivorax* can be responsible for aural or nasal myiasis.

The genus *Sarcophaga* (flesh flies) is capable of causing facultative myiasis. The adult fly is attracted to wounds or ulcers containing purulent and necrotic material. The adult fly deposits eggs in the open wound, where the larvae hatch.

Maggots seldom are found in the human intestinal or urinary tract.⁶⁵ Accidental myiasis can occur when humans ingest eggs or larvae and the larvae remain in the intestinal tract. Genitourinary myiasis is thought to occur by the deposition of eggs around the external urethral orifice. The larvae then may migrate into and up the urethra. Such situations should be called *pseudomyiasis*⁸¹ because the maggots are not living parasitically.

Clinical Manifestations

The lesions of cutaneous myiasis generally are located over the exposed area of the body. Early in the course of cutaneous myiasis, pruritus is the predominant symptom. As the larvae grow after the first week of infestation, a serous exudate may drain from the penetrating site. At this point, pain and pruritus are prominent symptoms and the lesion appears as a small furuncle (furuncular myiasis).²⁷ Tissue destruction by the larvae may continue, and secondary bacterial infection can occur. *Staphylococcus aureus*, group A streptococci, and gram-negative organisms have been isolated from infected cutaneous myiasis wounds.

Abdominal pain, diarrhea, and anal bleeding are the symptoms of intestinal myiasis, which is self-limited and may last 2 to 6 weeks. Larvae within the genitourinary tract may lead to proteinuria, dysuria, hematuria, and pyuria. Nasal myiasis can extend into bone, sinus cavities, and even the meninges.⁴ Aural myiasis has been described in a child without underlying disease.²⁰ Ophthalmomyiasis is characterized by an acute catarrhal conjunctivitis.²⁷ Penetration into the brain has been associated with intracerebral hematomas.⁴⁷

Diagnosis

A careful history of travel, occupation, and exposure is necessary to establish the diagnosis when the physician is confronted with unusual skin lesions that are pruritic and have not resolved with usual local care.^{39,44} Myiasis is confirmed if larvae are demonstrated within the wound. A parasitologist or entomologist may be able to identify the species of larvae responsible.

Treatment

The removal of the larvae is necessary in any of the forms of myiasis. Endoscopic removal of nasal infestation is recommended. Surgical intervention may be required to expose the larvae in the wound. Forceps are used to pick out the larvae; the application of 5% chloroform in olive oil may facilitate removal. Occlusive coverings of the wound opening are helpful in extruding *Dermatobia* larvae because this tends to diminish the oxygen supply for the larvae. A thick layer of petrolatum jelly (Vaseline) effectively interrupts the airflow.⁵³ Local or systemic antibiotics may be required if secondary bacterial infection is present.

The prevention of human myiasis requires good wound care, adequate personal hygiene, screening to protect against flies, and the prevention of myiasis in domestic animals.

MITES

As mentioned earlier, mites belong to the same class of arthropods (Arachnida) as ticks, spiders, and scorpions. They, too, can be vectors for infectious agents. The house mite, *Liponyssoides sanguineus*, is the vector for rickettsialpox (Chapter 195) agent. Chiggers, which are larvae of mites (family Trombiculidae), transmit to humans the agent responsible for scrub typhus, *Rickettsia tsutsugamushi*.

Some mites transmit no specific disease but can cause an annoying pruritic rash. In 2004, the microscopic itch mite (*Pyemotes herfsi*) was identified as a likely cause of an intensely pruritic skin reaction in individuals living in several Midwestern states, as well as Texas and Oklahoma. Skin lesions were papular and erythematous and occurred primarily on the face, neck, and limbs.¹²

Scabies, an extremely pruritic skin infestation, has been known for more than 2500 years. The etiologic agent for this condition, *Sarcoptes scabiei* var. *hominis*, is an obligate human parasite that burrows into the epidermis, no deeper than the stratum granulosum.¹⁷ Scabies appears to have an increased incidence in 15-year cycles⁶⁴ and is transmitted person to person through direct and usually prolonged contact.

Pathogenesis

Mites of all developmental stages tunnel into the stratum corneum and deposit feces (scybala) behind them. Characteristically, the gravid female lays eggs in the tunnels.³⁸ Clothing and bed linens are thought to be less important in the transmission of the *Sarcoptes* mite. Because scabies is transmitted by skin-to-skin contact, sexual transmission occurs commonly, as does nonsexual spread in family settings.¹⁷ Epidemic outbreaks of scabies have been reported in hospitals and other institutions where people were living closely together and especially where poor sanitation predominated.⁶

Hypersensitivity of both immediate and delayed types has been implicated in the development of lesions other than burrows.¹⁷ Papulovesicular scabies is characterized by perivascular lymphohistiocytic infiltrates with eosinophils. The papillary dermis is edematous. The histologic appearance of nodular scabies is one of a dense, superficial, and deep perivascular lymphohistiocytic infiltrate with many plasma cells and eosinophils. Various vascular changes also may be apparent.

Clinical Manifestations

Scabies is characterized by moderate to severe pruritus that starts several weeks to months after infestation, at which time the host has become hypersensitive to the mite or its products. Itching, most evident at night, is the primary symptom of infection. A papular or vesicular eruption with pustules and linear burrows occurs and classically involves the webs between the fingers, flexures of the arms, axillae, and genital regions of adults. In infants and children, scabetic lesions more typically occur on the palms, soles, head, and neck in the form of vesicles, pustules, or nodules. In this age group, scabies often is not suspected because of the atypical skin lesions that result from vigorous scratching and secondary infection.⁴²

Acute glomerulonephritis may be associated with pyoderma in scabies. A careful history may reveal that other family members or child caretakers have pruritus and skin lesions consistent with scabies. Examination of the skin of family members for signs of scabies frequently is helpful. Crusted scabies, previously known as Norwegian scabies, occurs in immunocompromised patients, especially those on immunosuppressive medications or those with HIV or human T-lymphotropic virus type 1 infection.³⁵ In this condition, mite replication is uncontrolled by the host's immune system.^{22,35} It is a psoriasiform dermatitis, frequently associated with a generalized or localized nonspecific hyperkeratosis.^{28,35}

Diagnosis

Definitive diagnosis can be made by microscopic identification of the mites, eggs, or mite feces.⁴³ To obtain this material, skin scrapings should be taken from papules or the end of a burrow or from underneath the surface of fingernails. In some cases, a variety of biopsy techniques can be useful.⁹ The diagnosis should be considered when the physician is faced with an unusual papular or bullous rash. The differential diagnosis of scabies in children includes impetigo, atopic eczema, seborrheic or contact dermatitis, psoriasis, histiocytosis, and chickenpox.^{42,43}

Treatment

The management of scabies involves the application of a topical scabicide to all areas of skin, including the face and scalp, with subsequent removal in 8 to 24 hours, depending on the product applied. An effective scabicide used in the past was gamma-hexachlorocyclohexane (lindane). It is no longer recommended for use in children because of concerns regarding neurotoxicity.^{22,50} Currently, effective topical scabicides licensed in the United States include 5% permethrin and 10% crotamiton. Although 5% malathion lotion is approved in the United States for treatment of head lice (see later discussion of head lice treatment), it has not received US Food and Drug Administration (FDA) approval to be used as a scabicide.³⁸

The agent of choice for infants and young children is 5% permethrin topical cream, applied in the evening to the entire head, neck, and body of the infant and left on overnight.⁴² It is indicated and safe for use in newborns and young children, as well as pregnant and lactating women.³⁸ A second application generally is recommended 1 to 2 weeks after the first dose.^{22,38} All family members should be treated simultaneously.⁵⁸ Antibiotics may be necessary if secondary bacterial infection is present.

The CDC has recommended the off-label use of oral ivermectin 200 µg/kg per dose given with food for the treatment of scabies, although the FDA has yet to grant such approval.²² Ivermectin is considered to be highly efficacious as an oral therapy for scabies in a single dose for otherwise healthy or HIV-infected adults.⁵⁴ Some have recommended two doses, with the second dose given 1 to 2 weeks after the first dose, especially for crusted scabies.²² In an Australian study involving more than 2000 participants, enrollees were randomly assigned to treatment with either topical permethrin or an oral dose of ivermectin. From baseline to 12 months, scabies prevalence declined for all participants, with the greatest reduction in the ivermectin group.⁶⁰

It works against several different parasites by interrupting gamma-aminobutyric acid–induced neurotransmission.¹⁷ The CDC recommends not using ivermectin in pregnant or lactating women and states that safety has not been determined in children who weigh less than 15 kg.

A pharmaceutical preparation (moxidectin), currently being used to treat mange in animals, is under consideration for possible treatment of human scabies. Pending study results as to efficacy and safety in humans, this may become available as a single-dose treatment in the near future.⁵⁵

From a global perspective, the International Alliance for the Control of Scabies was established in 2012. The organization is committed to the control of human scabies infestation and to promoting the health and well-being of all those living in affected communities. Priority areas have included advocacy, epidemiology, control strategies, and biological research.³²

Articles of clothing and bed linens should be machine washed in hot water at 60°C (140°F). Insecticidal powder or aerosol should be reserved for materials that cannot be washed.¹⁷ Pruritus often persists for some time after successful treatment with a scabicide and may be relieved by an oral antihistamine or mild to moderate topical steroids.^{9,58} In hospitalized patients, contact isolation is recommended to lessen the potential for nosocomial transmission.

LICE

Pediculosis

Arthropods of the order Anoplura (sucking lice) are important as vectors of rickettsial or spirochetal illnesses. The body louse, *Pediculus humanus humanus*, is the vector for epidemic typhus (*Rickettsia prowazekii*), trench fever (*Bartonella quintana*), and louse-borne relapsing fever (*Borrelia recurrentis*). The body louse, head louse (*Pediculus humanus capitis*), and crab louse (*Phthirus pubis*) all are capable of achieving human infestation. Pediculosis has been a problem for humans for more than 10,000 years.¹⁷

Pathogenesis

Head lice are the most common type of louse, affecting more than 100 million people worldwide each year.¹⁶ Tiny, they measure no more than 1 to 4 mm in length. They have six legs, each with powerful claws allowing firm attachment. Mouth parts consist of stylets (retracted when not in use) modified for piercing and sucking. When they are not feeding, lice are translucent, with gray-white bodies, but when engorged with blood, they become red. Each female is capable of laying as many as 300 eggs (nits) in a brief lifetime of 1 to 3 months. These eggs are less than 1 mm in diameter and hatch in 6 to 10 days, giving rise to nymphs. During a period of 10 days, the nymphs become adults. Schoolchildren of all socioeconomic groups are affected, with head-to-head contact being the most common means of transmission.

Clinical Manifestations

Children or adults with head lice usually have white or opalescent nits attached to individual strands of hair. The lice themselves firmly adhere to the base of the hair shaft, millimeters from the scalp. After a louse pierces the skin, a poisonous salivary secretion is exuded, resulting in pruritic dermatitis. Itching is the primary symptom in acute cases.

Body lice occur when socioeconomic conditions are poor. Infestation occurs when people fail or are unable to wash their clothes regularly, such as those living in refugee camps. Intense itching is a major problem, with noticeable excoriations and occasional secondary infections.

Pubic lice are transmitted primarily through sexual contact, although not exclusively so. In children, pubic lice generally occur from nonsexually transmitted contact with an infected parent. Again, itching is a major presenting symptom. Pubic lice may become attached to other hairy areas of the body, such as the axillae of adolescents, the eyelashes of children, and the scalp hair of any age group.¹⁷

As mentioned, body lice can function as vectors for the transmission of several diseases. One of these is trench fever, caused by *B. quintana*. Although some patients may have no symptoms, others may have fever, myalgias, headache, meningoencephalitis, transient maculopapular rashes, or chronic adenopathies. A second potentially transmitted disease is epidemic typhus, caused by *R. prowazekii*. Signs or symptoms of this infection may include fever, pruritic rash, headache, and confusion. Relapsing fever caused by *B. recurrentis* is the third disease known to be transmitted by the body louse.¹⁷

Diagnosis

Head, body, and pubic lice are visibly recognizable. The nits of head lice are attached firmly to hair shafts and are distinguished readily from dandruff flakes, lint, and other debris, which can be easily removed

from the hair. Viable nits, located close to the scalp, are oval and gray-white to yellow-white. Empty nonviable nits, attached at some distance from the scalp, are almost completely clear. Although difficult to see with the naked eye, nits visibly fluoresce yellow-green under Wood lamp. PCR helps identify host DNA from lice through their blood meal, providing valuable information for rape, homicide, and child abuse cases.⁵¹

The body louse has been demonstrated as the true vector of trench fever by using PCR to detect within them the *B. quintana* DNA from infected patients.⁸ Detection of rickettsial DNA in body lice has confirmed the presence of human typhus.

Treatment

Head lice. Numerous forms of treatment for the eradication of head lice have been used. Over the course of time, resistance developed to several of these forms of therapy. Gamma-hexachlorocyclohexane (lindane) shampoo was used almost exclusively until the early 1970s. Because of concern about potential neurotoxic effects for the patient, it no longer is recommended as a first-line medication for children.⁵⁰

A systematic review (1995) concluded that sufficient evidence existed only for the use of a pyrethroid insecticide, 1% permethrin cream rinse.^{16,73} This biodegradable and generally very safe product remains the recommended first-line therapy. It should be applied to wet hair and left in place for about 10 minutes before rinsing. Because of variable reports of head lice resistance to 1% permethrin, the current recommendation is two treatment applications 7 to 14 days apart, or even three treatments at 0, 7, and 15 days, based on the life cycle of head lice.⁵ Some success has been reported with use of a 5% permethrin preparation and wearing a shower cap overnight.⁶¹ To remove the firmly adherent nits, a fine-toothed stainless steel comb (LiceMeister) has been recommended.

Malathion lotion 0.5%, an organophosphate, has been an excellent alternative to the use of permethrin in areas where head lice resistance has occurred. When applied to the hair and left in place for 8 to 12 hours, it provides residual protection. The intent is to use it for those older than age 6 years. Live lice will be killed, but not all eggs. A second treatment 7 to 9 days later can be used if live lice remain. Caution should be taken because it is potentially flammable. Those treated should not be exposed to open flames or electric heat sources, including hair dryers and electric curlers.^{1,5}

Cases of resistance to the malathion-containing formulation have been reported in Europe, but that product is different from the one licensed in the United States. The latter contains additional synergistic agents, including 78% isopropanol. Because it is hydrolyzed and detoxified by plasma carboxylesterases much more rapidly in mammals than in insects, it is considered safe. Although it is contraindicated for use in infants, the American Academy of Pediatrics considers it safe for use in children 2 years and older.^{1,5}

Ivermectin has been used when other medications have failed. For those at least 6 months of age, ivermectin lotion 0.5% was approved by the FDA in 2012. A single application to dry hair is considered effective in most patients. Although not approved by the FDA for the treatment of head lice, ivermectin in a single oral dose of 200 µg/kg has been effective. If needed, a second dose of 400 µg/kg 9 to 10 days later can be given. Concern exists when the drug is used in patients weighing less than 15 kg or in those who are pregnant or breast-feeding.¹⁰

As a result of reports of difficult-to-treat head lice infestation, authors in one cluster-randomized, double-blind, double-dummy, controlled trial compared ivermectin 400 µg/kg to the application of 0.5% malathion lotion, each given on days 1 and 8. Ivermectin was reported to have superior efficacy. However, the malathion product was not the one licensed in the United States.¹⁶

In addition to malathion, two other topical pediculicides have received FDA approval for pediatric use. Labeled for use in children 6 months or older, benzyl alcohol should be applied to dry hair for at least 10 minutes. If live lice persist, a second application should be administered 7 days later. For children 4 years of age or older, spinosad should be applied in the same way as benzyl alcohol.

There have been other recommended approaches to the treatment of head lice, all with somewhat limited success. A short course of oral

trimethoprim-sulfamethoxazole had been recommended in the past with the intent of destroying essential lice gut bacteria, responsible for the production of vitamin B, essential for continued life. A nonchemical approach to treatment has been the application of a topical lotion (Cetaphil Skin Cleanser) to the hair, with subsequent use of a blow dryer to “shrink-wrap” and ultimately suffocate lice.⁵⁷ Although this approach may result in significant success, the original study was not sufficiently rigorous to prove its effectiveness.

The use of a high-volume, hot-air blow dryer alone has been reported to have killed 94% to 98% of lice eggs and 76% to 80% of hatched lice.³⁷ When examined 1 week later, virtually all of the patients were completely cured. Although promising, this approach necessitates further testing by independent investigators. If proved efficacious, it could potentially eliminate the use of chemicals, to which some lice have become resistant.

Body lice. A general recommendation has been thorough washing of the body with soap and water followed by the application of a pyrethrin or pyrethroid or malathion for 8 to 24 hours. Again, caution should be taken in the use of these preparations in children. Decontamination of clothing and bed linens is essential by either washing them in hot soapy water at a temperature of 54°C (130°F) for 10 minutes or placing them in a hot clothes dryer for 20 minutes.

Pubic lice. Treatment should be similar to that used for managing head lice. Clothes and bed linens should be decontaminated. In the case of children, parents also should be treated; and in the case of adolescents, sexual partners require treatment.

BED BUGS

Numerous recent reports have documented the reemergence of bed bugs (*Cimex lectularius*) as a cause of pruritic, erythematous papules.^{14,70} Although they are known to harbor pathogens (e.g., plague and hepatitis B), bed bugs are considered incapable of transmitting those diseases to humans^{45,74} and therefore are not thought to pose a medical threat. Secondary skin infections, however, can develop as a result of persistent scratching, and allergic reactions are a possibility.

The upsurge in bed bug infestation has been attributed to various factors, including increased international travel and transport, exchange of secondhand furniture, insecticide resistance, and changes in insecticide use.²³ The primary result of contending with these annoying insects has been both social and psychological. Hotels, department stores, apartment buildings, and homeowners have encountered a significant economic loss in their efforts to eliminate these pests.

Pathogenesis and Clinical Manifestations

Bed bugs tend to be nocturnally active and are attracted to humans by warm body temperature and the exhalation of carbon dioxide. Most can be found within 5 feet of the bed. Survival depends on blood extracted from their respective hosts, which is achieved by piercing the skin with their beadlike proboscis containing a set of two hollow tubes. Online videos are available for viewing actual bed bug feeding.²⁵ Through one of these tubes, they inject saliva containing both anticoagulants and anesthetics; through the other one, blood is withdrawn.⁷⁰ Although they can live for up to 18 months without feeding, bedbugs typically seek blood every 5 to 10 days.

Feeding time generally takes place in the early morning hours, when the host is most calm and least likely to sense the presence of a crawling insect. Because bed bugs are opportunistic feeders, shift workers, who sleep during the daytime, also are vulnerable.

Total feeding time can range from as short as 5 minutes to as long as 30 minutes, after which the insect abandons the skin surface and seeks seclusion among bed sheets, blankets, mattresses, floorboard cracks, or other crevices.⁷⁰ The host generally does not experience itching or skin irritation until several minutes or hours after the insect has fed. In some cases, no skin reaction occurs at all.

Diagnosis

Suspicion for the possible presence of bed bugs occurs when the host awakens with itching and visible bites not present before going to sleep. Clues to the presence of bed bugs include discrete red-brown bloodstains

on sheets and mattresses, as well as flecks of excrement at the portals of hiding places.⁶⁸ Confirmation requires finding and identifying these bugs. Current approaches to early detection include the use of various lures or traps and training dogs to pick up the scent of certain bed bug pheromones.²³

Treatment

Treatment of bites is relatively conservative, directed toward symptomatic relief of itching, irritation, and secondary infection. Antipruritic medication, either topical or oral preparations, may be considered. First-generation antihistamines can help alleviate the itching but may be sedating. Topical corticosteroids can help reduce the erythema and itching. Oral antibiotics alone are sufficient to treat secondary bacterial skin infections.

Eradication

Insecticides containing pyrethroids are used widely as a control measure; however, pyrethroid-resistant bed bug populations have been found in some states. Nonchemical methods to effectively control bed bugs include heating infested rooms to 48°C (118°F) for 1 hour or cooling rooms to -16°C (3°F) for 1 hour; encasing mattresses and box springs with bed bug-excluding covers; and vacuuming, steaming, laundering, and disposing of infested items. Any effective control measure for bed bugs requires support from all residents in affected buildings and ongoing monitoring for infestation from other housing units. In addition, multiple inspections and treatments frequently are needed.

In a relatively recent report, a total of 111 illnesses, representing seven different states, were associated with bed bug–related insecticide use. The majority of the illnesses were of low severity (81%). One fatality was confirmed. The most common factors contributing to illness were excessive insecticide applications, failure to wash or change pesticide-treated bedding, and inadequate notification of pesticide application.¹⁵ To rid the living environment of bed bugs, a professional exterminator should be consulted.

SPIDERS

Of the thousands of species in the United States, only a few pose a threat to humans. Species of the genus *Loxosceles* are the spiders predominantly responsible for necrotic arachnidism in the United States. The two most common species are the black widow spider (*Loxosceles mactans*) and the brown recluse spider (*Loxosceles reclusa*). Both prefer dark, undisturbed habitats, such as outdoor lavatories, woodpiles, underside of stones, or dark corners of garages and attics. The black widow has a characteristic red hourglass shape on its ventral surface. The brown recluse has a violin-shaped marking over its dorsal surface. In the Pacific Northwest area of the United States, the hobo spider (*Tegenaria agrestis*) produces an envenomation similar to that of the brown recluse spider.¹¹

Pathogenesis

Venom from the black widow contains a neurotoxin (α -lactrotoxin), not a tissue toxin. The main effect is at the presynaptic membrane of the neuromuscular junction. Venom from the brown recluse spider contains sphingomyelinase D, a phospholipase that induces dermal necrosis and also causes systemic effects through its interaction with red blood cells, platelets, and endothelium.⁶² The necrosis caused by the venom depends on neutrophils, but the neutrophils are not activated by the venom itself. Rather, the venom is a potent stimulus for the inflammatory response of endothelial cells, which in turn activates the polymorphonuclear neutrophils to cause tissue destruction.⁵⁶

Clinical Manifestations

The bite of the black widow spider generally is painless, but a target lesion may develop. Within 30 to 120 minutes, some patients complain of regional lymph node tenderness.⁸⁰ The primary symptom that follows the bite is muscle cramping, generally involving the abdomen, chest, or back, depending on the location of the bite. Autonomic symptoms, including profuse sweating, nausea, vomiting, and tachycardia, may occur.⁶² Hypertension can be a significant problem. The degree of systemic

symptoms depends on the amount of venom injected and the number of bites. Severe cases may progress to internal hemorrhage, paralysis, and, rarely, even death.

The brown recluse spider bite may produce a mild or sharp stinging sensation. After several hours, the pain intensifies and itching occurs.² Eventually, a blister with surrounding erythema forms at the site. In the course of time, the lesion becomes larger, and central necrosis develops. Systemic signs developing in the first 24 to 48 hours may include headache, fever, nausea, vomiting, and joint pain. Disseminated intravascular coagulation, multiorgan failure, and death have been reported in children.^{36,78}

Like that of the brown recluse spider, the bite of the hobo spider may result in a central necrotic area. The most common systemic symptom is a severe headache. Protracted systemic effects, including aplastic anemia, intractable vomiting, and profuse secretory diarrhea, are rare occurrences but may be associated with death.⁷⁵

Treatment

For the patient who has been bitten by a black widow spider, analgesia is the mainstay of care.⁶² An antivenin is available, but only for the most severe cases of envenomation, unresponsive to other measures.⁷

For bites of brown recluse spiders, numerous treatments have been used, including hyperbaric oxygen therapy, early excision, antibiotics, dapsone, and corticosteroids. Careful supportive care, including monitoring of electrolytes and renal function, is required if symptoms are severe.⁶² Systemic corticosteroid therapy may be of some benefit if the patient has considerable symptoms. Dapsone, an inhibitor of neutrophil function, appears to decrease the development of wound complications and subsequent need for surgical excision.⁵⁹

SCORPIONS

Scorpions, like ticks, mites, and spiders, belong to the Arachnida class of arthropods.³⁰ The striped bark scorpion (*Centruroides vittatus*) is the most common type of scorpion found in the United States.²⁹ The most dangerous and perhaps the most lethal scorpion in this country is *Centruroides exilicauda* (former species name, *sculpturatus*), occasionally referred to as the bark scorpion.^{31,62} It is indigenous to the desert Southwest, particularly Arizona. Depending on the species, scorpions tend to reside in cracks and crevices, in cupboards and closets, or under loose tree bark. They inject their venom when disturbed or threatened.

Pathogenesis and Clinical Manifestations

C. vittatus produces a neurotoxic venom stored in poison glands in the tip of the tail. The venom of these scorpions is deadly to insect prey and produces a painful sting for humans. For those allergic to the sting, an anaphylactic reaction may occur.²⁹ The venom from the *Vaejovis carolinianus* (plain eastern stripeless scorpion) is considered to be mild, similar to that of a honeybee sting. Anecdotal reports indicate that on occasion, a severe reaction may occur.³⁰ The *C. exilicauda* scorpion produces a neurotoxic venom that can lead to cardiac failure, respiratory paralysis, agitation, paresthesias, hypersalivation, hypertension, and gastrointestinal symptoms. Although tachycardia and hypertension are frequent reactions, opposite effects are a possibility when the venom activates the parasympathetic nervous system.⁵⁹ The absence of local tissue reaction is helpful in distinguishing *C. exilicauda* stings from those of other scorpions found in Arizona.³¹ Children and elderly adults are most at risk as a result of envenomation from *C. exilicauda*.²⁹

Treatment

Most scorpion stings necessitate only nonprescription analgesic medication. For the management of *C. exilicauda* envenomation, atropine can be used to control hypersalivation, although it could be contraindicated when the sting has been produced by scorpions foreign to the United States. In some of those cases, the use of atropine can exacerbate an adrenergic toxicity reaction created by the sting of the scorpion. Treatment of *C. exilicauda* envenomation with an antivenin (available in Arizona only; not approved by the FDA) has been reported to provide relief from the neurotoxic effects. It has the unfortunate potential of causing both immediate and delayed hypersensitivity reactions.^{31,62}

FLEAS

Murine Typhus

Also known as endemic typhus fever, murine typhus is a worldwide flea-borne infection of humans. It is caused by *Rickettsial felis* and *Rickettsial typhi*. The disease most commonly occurs among people in contact with rats or areas where rats live, but also occurs among people who live near or have contact with other small mammals (e.g., opossums and cats). Cases reported in the United States are usually confined to suburban areas of Texas and Southern California, as well as several Hawaii islands. The cat flea *Ctenocephalides felis* is considered to be the primary vector.¹⁸ The disease is often difficult to diagnose because of its nonspecific clinical presentation. Clinicians are led to believe that patients have other, more commonly seen vector-borne infections, such as dengue fever, ehrlichiosis, West Nile virus, and Rocky Mountain spotted fever, or non-vector-borne infections (e.g., bacterial or viral meningitis disease, Kawasaki disease, or secondary syphilis).¹⁸

Pathogenesis and Clinical Manifestations

Like other rickettsiae, *R. typhi* is a small (0.4–1.3 mm) gram-negative obligate intracellular bacterium depending on hematophagous arthropods (e.g., fleas and ticks) and mammals to maintain its life cycle. *R. typhi* multiplies in the epithelial cells of the flea midgut and subsequently are shed into the feces, which in turn are deposited on the host skin surface while the flea is feeding.¹⁸ Humans and other mammals acquire the bacteria when the flea bites or feces are inoculated into the bite site.³ *R. felis* has been identified as the cause of typhus-like illness in the United States (Texas), Mexico, France, and Brazil. Molecular studies have found that *R. felis* and *R. typhi* are indistinguishable serologically and require separate identification using PCR analysis.¹⁸

Following an incubation period of 1 to 2 weeks, the most common symptoms include 3 to 7 days of fever, headache, exanthema, and arthralgia. The exanthema can be variable from patient to patient. It can be macular or maculopapular and nonpruritic, beginning on the trunk, eventually spreading to the arms and legs, but sparing the palms and soles. It appears about 7 days after the onset of fever and remains unchanged for a period of 1 to 4 days.¹⁸

The mortality rate for murine typhus is low with use of appropriate antibiotics (1%) and about 4% without the use of antibiotics. In most cases, it will present as an acute, self-limited illness without complications. However, serious complications have been associated with acute infection, including endocarditis, splenic rupture, and aseptic meningitis.¹⁸

Diagnosis

Most rickettsial infections are diagnosed using serologic methods such as IFA, often considered to be the most ideal test. Unfortunately, serologic studies are rarely diagnostic when blood specimens are collected at the onset of symptoms. A convalescent-phase specimen, yielding a fourfold increase in titer between the acute- and convalescent-phase samples, is usually required to confirm the diagnosis.^{18,79}

Other available serologic assays include the indirect immunoperoxidase assay, latex agglutination, line blot, and Western immunoblot. Isolation of rickettsiae from blood cultures is rarely successful and usually necessitates the expertise of a specialized research laboratory. Diagnosis has been made by PCR with the use of peripheral blood, buffy coat, and plasma specimens and occasionally with fresh-frozen or paraffin-embedded tissue specimens or with arthropod vectors acquired during ecologic surveillance (i.e., cat fleas).^{18,79}

Treatment

Antimicrobial testing is not routinely performed on rickettsiae. As with other rickettsial diseases, the preferred antibiotic is a tetracycline, particularly doxycycline for children 9 years and older. The course of treatment is usually a week or less, limiting the risk for dental staining.^{13,77}

Tungiasis

Tungiasis, also known as sand flea disease, is a parasitic skin infestation. It is indigenous to parts of South America and sub-Saharan Africa. The population most vulnerable are children and elderly people, living in impoverished, resource-poor areas. *Tunga penetrans* and *Tunga trimamillata* belong to the genus *Tunga* of the order Siphonaptera. They are unique among other fleas in that the nonfertilized females of these species burrow into the skin, but only minimally advance further. Staying in situ, they subsequently die off in 4 to 6 weeks. During this time, their distal segment remains exposed to the open environment, allowing them to breathe, defecate, copulate, and expel eggs. The entry site becomes a portal for access by infectious microorganisms.³³

The primary penetrance site is the sole of a bare foot. However, any body part is vulnerable, especially if the person is sleeping on the floor or ground. Marked erythema, pain, edema, and itching are present. Aerobic and anaerobic bacteria, adherent to the flea or introduced by scratching the skin site, are provided a pathway for producing a subsequent infection. Particularly in impoverished areas of the world lacking appropriate immunization access, tetanus is not an uncommon occurrence.³³

In addition to humans, a broad spectrum of domestic and sylvatic animals is also susceptible to infiltration by the sand flea. Treatment to eliminate the burrowed flea has met with limited success. Many individuals have attempted removal using nonsterile sharp instruments or sharpened pieces of wood. One field application involved a combination of 10% imidacloprid and 50% permethrin, providing temporary reduction in the parasite load. Another preventive had been the application of a plant-based repellent, Zanzarin. More recently, the topical application of a mixture of two low-viscosity dimethicones has met with some degree of success.^{33,71}

Despite the large number of people affected by sand flea infestation, especially in resource-poor countries, and limited treatment options, tungiasis remains unlisted by the World Health Organization as a neglected tropical disease.

The keys to success as a global health professional are compassion, competence, critical thinking, and creative adaptability.

Chunhuei Chi

This chapter provides an introduction to the definition, evolution, disciplinary perspectives, interventions, and contemporary challenges associated with global health. For information on specific health conditions and infectious diseases of global concern, such as human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS), malaria, tuberculosis, parasites, or specific circumstances, such as international adoptions, the reader is referred to the individual chapters for each of these entities.

DEFINITION OF GLOBAL HEALTH

The term global health is widely used and very popular among academic institutions, humanitarian and government agencies, nongovernment organizations (NGOs), and nonprofit organizations around the world.³⁰ Global health is increasingly mentioned as an area of public health and medical professional interest, as well as a philanthropic goal, but it is rarely defined by a definition agreed on by even the most influential health organizations.^{2,4,27} Many organizations and institutions have used the term global health as a state of being or condition, as a goal, or as a field of study that relates to education, research, and practice. Uniformity of definition is desirable because it sets the foundation for collaborative efforts of global purpose, clear objectives for action, and reliable instruments for measuring achievements. Fragments of public health and international health definitions, which evolved from hygiene and tropical medicine, have been used to assemble a concept of global health that is becoming universally accepted.^{5–7} Global health often overlaps in the fundamental purpose and initiatives of both public and international health and can be seen as evolving from both disciplines. An understanding of the history and evolution of definitions of health, public health, and international health is helpful in understanding the overall objective of global health.²⁷

The World Health Organization (WHO), one of the leading authorities for health, has defined health as “a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity.”²⁸ This definition was the basis from which the WHO worked their evolving and emerging projects toward the goals to improve the overall health of the world. This definition is broad and all inclusive. It includes the larger picture of overall health for one person, or a whole community, and covers not only the administration of medical attention, but also prevention of disease through public health, policy, mental well-being, research, and many more factors influential in health.

The current public health concepts emerged in mid-19th-century Europe and the United States. During this time, medical advances in the cause, management, and prevention of infectious diseases and the growth of social reform movements helped establish the discipline of public health with four main concepts: (1) decision making based on data and evidence gathered through vital statistics, surveillance, outbreak investigations, and scientific method; (2) focus on populations or groups rather than individuals; (3) action rooted in social justice and equity; and (4) prevention of disease rather than treatment or cure of established disease. In 1988, the Institute of Medicine reconfirmed public health as a preventive discipline that uses a community approach and involves multiple partners working toward a common good of public health.

The American Public Health Association (APHA) defines public health in contemporary terms as “the practice of preventing disease and promoting good health within groups of people, from small communities to entire countries,” including the well-being of the population of a specific country or community within a country.⁵ Public health practice emerged from the works of many pioneering scientists and physicians and the early discoveries about quarantine, sanitation, and housing; public knowledge on sexually transmitted infections and diseases; and vaccinations. Eventually, the practice of public health evolved from early efforts of individuals to organized efforts among societies and nations.

The field of international health was further developed from public health, hygiene, and tropical medicine disciplines as medical missionaries, scientists, and other humanitarians traveled and shared their discoveries and new ideas. The specific focus of international health and international medicine currently lies in the differences among countries, peoples, and regions. International health applies the well-established public health principles of industrialized countries to assist the health problems and challenges of low-income populations in developing countries, through foreign aid activities and missionary work (Table 231.1). It often includes “diseases of the developing world” and “health work abroad,” with a focus on infectious and tropical diseases, water and sanitation, malnutrition, and maternal-child health.^{5–7} Previously, international health and global health were considered interchangeable terms, whereas now most experts recognize them as distinct disciplines and practices.²⁷

Global health transcends the individual nations and borders and emphasizes worldwide improvement of health, reduction of disparities, and protection against threats to health of the people of all nations (see Table 231.1). Global health focuses on the similarities throughout the world and the issues that cross nations.²⁷ It blurs the borders to create a sense of unity and understanding of how people, cultures, and the environment interact and affect each other. It emphasizes both the individual and the population and strives for equity among people of all nations. It also is highly interdisciplinary and multidisciplinary in its approach to problem solving and strives to provide creative and sustainable solutions for resource management in resource-poor regions (see Table 231.1).

Current global health issues involve not only the direct health impact, but also other disciplinary perspectives that indirectly influence health, such as climate change and natural disasters, economics, politics, conflict, war, migration, food crisis, energy crisis, and neglected diseases.¹ The political perspective of global health emphasizes the influences of war and economy on the health of the world. The educational and research perspectives of global health are evident when global health is taught as curriculum in both medical and sociologic disciplines and are an educational goal of many institutions of higher learning. The epidemiologic perspective of global health identifies and follows trends of major global health threats and partners with the medical perspective to describe the pathologic factors, clinical manifestations, diagnosis, treatment, and prevention of these diseases. From an economic perspective, global health emphasizes cost-effectiveness and cost-benefit approaches for population health and includes the measurement of health burden, including life expectancy; adult, maternal, infant, and child mortality; disability; and quality of life.^{11,12,14} Many experts also view global health from the ethical and societal perspective and include educational disparities, reproductive health, violence against women and children, and child labor and hawking laws as global health concerns.

TABLE 231.1 Comparison of Global, International, and Public Health

Comparison Factors	Global Health	International Health	Public Health
Geographic reach	Focuses on issues that directly or indirectly affect health but that can transcend national boundaries	Focuses on health issues of countries other than one's own, especially those of low and middle income	Focuses on issues that affect the health of the population of a particular community or country
Level of cooperation	Development and implementation of solutions often require global cooperation	Development and implementation of solutions usually require binational cooperation	Development and implementation of solutions do not usually require global cooperation
Individual or populations	Embraces both prevention in population and clinical care of individuals	Embraces both prevention in populations and clinical care of individual	Mainly focused on prevention programs for populations
Access to health	Health equity among nations and for all people is a major objective	Seeks to help people of other nations	Health equity within a nation or community is a major objective
Range of disciplines	Highly interdisciplinary and multidisciplinary within and beyond health sciences	Embraces a few disciplines but has not emphasized the multidisciplinary	Encourages multidisciplinary approaches, particularly within health sciences and with social sciences

From Koplan JP, Bond TC, Merson MH, et al. Towards a common definition of global health. *Lancet*. 2009;373:1993–5.

HISTORY AND EVOLUTION OF GLOBAL HEALTH

The beginnings of the contemporary concepts surrounding global health evolved from European colonization and colonial enterprises. Colonialism affected the public health of the world at the time through the introduction and rapid spread of non-native diseases, such as measles, smallpox, and malaria to previous nonimmune indigenous people in Saint Domingue, Haiti, and the Americas. In addition, the extraction of wealth prevented the indigenous people from exiting the cycle of poverty and disease. Furthermore, colonization of Africa, India, and the Americas by the British and other Europeans created urban centers and crowding that bred infectious diseases such as cholera, tuberculosis, and smallpox and fueled the HIV/AIDS epidemic. In contemporary terms, international spread of disease, such as influenza pandemics, through international travel or potentially by bioterrorism, is a global health concern.

Medicine underwent a dramatic change in the late 19th century with the discovery of the germ theory of disease and the awareness of it in the public health consciousness.⁵ Proponents of the germ theory included Louis Pasteur, the father of the germ theory and early vaccinology; Robert Koch, father of Koch's postulates to establish a list of criteria to determine the cause of a disease; and John Snow, the father of modern epidemiology, who discovered the transmissibility of cholera and its prevention. In 1902, a model international collaboration to fight yellow fever created the Pan American Health Organization. After World War I, the League of Nations Health Committee changed its focus on infectious diseases to include nutrition and maternal and infant health. In 1947, the WHO was created by the United Nations to serve as a single global entity charged with fostering collaboration among member nations to work toward the new definition of health as a state of well-being and not merely the absence of disease. During this time the social determinants of health began to coexist with the advent of health care delivery and treatment of infections and other diseases.

This history of global health also has included disease eradication efforts. Smallpox, the first global disease to be eradicated, was declared eradicated in 1980 through the successful efforts of the WHO Smallpox Eradication Campaign. The achievement of smallpox eradication resulted not only from the possession of an effective smallpox vaccine but also through global cooperation that used intensive surveillance, disease reporting, and aggressive focus on immunization in every local community. Malaria, a disease demonstrated first by Ronald Ross to be transmitted by mosquitoes, was targeted for eradication by the Malaria Eradication Campaign of the WHO, using basic strategies of personal protection, mosquito reduction, and treatment of malaria disease. Unfortunately, despite these effective means of prevention and treatment of malaria, malaria remains a global health problem because most rural or resource-poor communities have not adopted these preventive and

curative health measures. This failure demonstrates the complexity of global health problems and highlights the interrelationships among health, infrastructure, culture, politics, and economics, and it emphasizes the importance of culturally sensitive programs. Other infectious diseases also now targeted for global eradication programs include poliomyelitis, trachoma, tuberculosis, rabies, and HIV/AIDS.⁴³

In the 1970s, a movement emphasizing primary health care in rural communities became increasingly popular. An example of such a movement were the “barefoot doctors” in China during the Cultural Revolution, who emphasized rural care and community-based health programs. In 1971, the NGO Doctors Without Borders was founded by French physicians who understood the importance of sociopolitical determinants of health. In 1978, the International Conference on Primary Health Care took place in Alma-Ata, the capital of the Soviet Republic of Kazakhstan, in the Soviet Union. From this conference emerged the Declaration of Alma-Ata, which stated that health was a fundamental human right and an important worldwide social goal and supported “Health for All by the Year 2000.” It also emphasized the importance of culturally sensitive, local, community-based programs as opposed to the top-down vertical programs that were previously used in the smallpox and malaria eradication campaigns.

From the broad concepts of primary health brought forth from the Declaration of Alma-Ata came selective and targeted goals for primary health care implementation. These programs included goals for measles and diphtheria-pertussis-tetanus vaccination, treatment of malaria, oral rehydration for diarrhea in children, encouragement of breastfeeding, and family planning. The goals, implementation, and success of targeted and focused strategies on specific disease prevention and treatment could also then be measured and assessed for political and philanthropic funding. Donations for global health were estimated to be more than \$10 billion dollars in 2000, and governments, agencies, companies, and individuals who fund global health initiatives now increasingly demand performance data in return for their financial aid.

Modern global health challenges include the ongoing balancing act between preventive public health initiatives and medical treatment interventions. A diagonal approach that synergistically incorporates both types of interventions is likely to be most successful. In addition, as industrialized development and economic progress spread globally, the challenge will be to emphasize the importance of local cultural sensitivity and avoid resource exploitation that may occur at the expense of the health of the local people. Global health indicators to monitor changes in the health of various populations are being advocated for both developed and developing countries.^{11,12,14} These indicators should be well defined and applied internationally in a uniform manner. They also should be valid, reliable, and readily interpretable measurements that can be feasibly gathered and affordably ascertained even in developing

countries, and they should be useful to decision makers who can easily act on the indicators at the local, national, and international level. Health indicators in developed countries often reflect lifestyles and individual behavior, such as diet, exercise, and smoking, whereas health indicators in developing countries focus on morbidity, mortality, and severe disease precursors of both these indicators.^{29,28} Global health indicators present a contemporary challenge, especially in resource-poor areas with little or no access to electrical power and where records of birth, growth, lifestyle, medical illness, or death are not systematically documented and kept.^{29,28}

Global health communication, public health awareness, and humanitarian efforts are also now facilitated through Internet use, mobile cellular phones, mobile applications, and social media. Through the power of the periphery that social media and mobile cell phones provide, people are able to expand their community and access not only information but also health care and transportation. In addition, many global health care organizations use cellular phones in remote or resource-poor locations to collect research data for social health projects or instantaneously log information into surveillance systems for outbreak investigations.

SOCIAL DETERMINANTS OF HEALTH

The social determinants of health reflect where people are born, grow, live, work, and age and represent a powerful influence on the global health and the global disease burden of all nations.⁴⁹ Disease is often directly and indirectly influenced by other social, political, economic, and environmental factors, which in turn are responsible for ongoing health inequalities or acute and urgent health crises. These social determinants of health include broad and general political, socioeconomic, cultural, and environmental conditions; social and community networks; individual and family lifestyle factors; and individual characteristics such as age, gender, and genetic or constitutional factors (Box 231.1).⁴⁹

MILLENNIUM DEVELOPMENT GOALS FOR GLOBAL HEALTH AND THE NEW SUSTAINABLE DEVELOPMENT GOALS

The Millennium Development Goals (MDGs) consist of 8 broad global health goals established and agreed on by all UN Member States and 23 supporting organizations of the world during a UN summit in 2000 (Box 231.2).^{45,46} The United Nations Millennium Declaration was adopted as a 15-year commitment to address the challenges facing human health globally and promote global development by improving social and economic conditions in the poorest countries, the “bottom billion,” by the year 2015.^{48,50,51} Goal 5 (MDG 4) “to reduce child mortality” and goal 5 (MDG 5) “to improve maternal health” specifically address pediatrics, and the sixth goal (MDG 6), “to combat HIV-AIDS, malaria, and other diseases,” specially addresses infectious diseases (Fig. 231.1).^{26,38,43,45}

Progress on the MDGs has been assessed through an initiative known as the Global Burden of Disease Study (GBD) based at the Institute for Health Metrics and Evaluation (IHME) at the University of Washington but ultimately involving hundreds of investigators internationally.^{34–36} MDG 4 and MDG 6 showed some of the greatest gains. For instance, for MDG 4 there was an international effort to increase access to the major childhood vaccines available at the turn of the 21st century, as well as to accelerate the development of pneumococcal and rotavirus vaccines. Many of these activities were led by Gavi, the Vaccine Alliance, a UN agency headquartered in Geneva, Switzerland. According to the GBD 2013, which examined progress from the years 1990 to 2013, there was a 50% to 80% decrease in the number of childhood deaths from measles, tetanus, whooping cough, *Haemophilus influenzae* type B pneumonia, and rotaviral enteritis, whereas deaths from pneumococcal pneumonia were reduced by more than one-third.³⁴

Similarly, with regard to MDG 6, there were also substantial gains for HIV/AIDS, tuberculosis, and malaria through the establishment of an international (and also Geneva-based) Global Fund to Fight AIDS, Tuberculosis, and Malaria (GFATM), as well as large-scale US government

initiatives such as the President’s Emergency Plan for AIDS Relief (PEPFAR) and the President’s Malaria Initiative for HIV/AIDS. GFATM and PEPFAR placed unprecedented numbers of people in low-income countries on antiretroviral drugs, whereas people with malaria in Africa and elsewhere had unprecedented access to antimalarial drugs and insecticide-treated nets. GBD 2013 found that through such efforts we

BOX 231.2 Millennium Development Goals Adopted by World Leaders at the United Nations in 2000 to Be Achieved by 2015

1. Eradicate extreme poverty and hunger
 - a. Halve the proportion of people living on less than US\$1 per day
 - b. Achieve decent employment
 - c. Halve the proportion of people suffering from hunger
2. Achieve universal primary education
 - a. Allow all children, regardless of gender, to complete a full course of primary schooling
3. Promote gender equality and empower women
 - a. Eliminate gender disparity in primary and secondary education
4. Reduce child mortality
 - a. Reduce the "under 5" mortality rate by two-thirds from the year 1990
5. Improve maternal health
 - a. Reduce the maternal mortality rate by three-fourths from the year 1990
 - b. Achieve universal access to reproductive health
6. Combat HIV/AIDS, malaria, and other diseases
 - a. Begin to reverse the spread of HIV/AIDS by 2015
 - b. Achieve universal access to treatment of HIV/AIDS by 2010
 - c. Begin to reverse the incidence of malaria and other major diseases by 2015
 - d. Reduce tuberculosis worldwide
7. Ensure environmental sustainability
 - a. Integrate the principles of sustainable development into country policy programs and reverse the loss of environmental resources
 - b. Reduce biodiversity loss and achieve a significant reduction in the rate of loss
 - c. Halve the proportion of the population without sustainable access to safe drinking water and basic sanitation
 - d. Achieve a significant improvement in the lives of at least 100 million slum dwellers
8. Develop a global partnership for development

HIV/AIDS, Human immunodeficiency virus/acquired immunodeficiency syndrome.
Data from references 45 and 46.

have reversed the alarming rise of deaths from HIV/AIDS in Africa and elsewhere while simultaneously reducing deaths from malaria by approximately one-third, in addition to reducing the case-fatality rate from tuberculosis.³⁵ There have also been important reductions in the "other diseases" component of MDG 6, sometimes referred to as the neglected tropical diseases (NTDs), which includes the major helminth infections and trachoma.¹⁶ Most of these gains have resulted from widespread use of a "rapid impact" package of essential NTD medications administered in programs of integrated mass drug administration.¹⁶ It is estimated that almost one-half billion people have received partial or complete packages with substantial reductions in NTDs such as lymphatic filariasis, onchocerciasis, and trachoma,⁴⁷ to the point where it is believed that elimination of these diseases may be possible in the coming decade. For other NTDs, such as dengue fever, hookworm, and schistosomiasis, additional interventions may be required.

According to IHME, the impact of these reductions in deaths and morbidities from infectious diseases has been associated with a commensurate rise in noncommunicable diseases, especially diabetes, cardiovascular diseases, and cancer.³⁶ These findings have led to the formation of a Lancet Commission to establish a "Global Health 2035" initiative calling for new legislation and other activities to reduce the risk for noncommunicable diseases including policies aimed at limiting access to tobacco, alcohol, and other risk factors.²⁵ Still another important global health trend that has been noted are the high rates of neglected diseases, including NTDs, and HIV/AIDS, tuberculosis, and malaria noted among poor people living in wealthy Group of 20 countries. The term "blue marble health" has been coined to describe a changing global paradigm in which many economies are rising but leaving behind the poor with these diseases.^{18,19,22,23} This finding explains why more than 10 million Americans live in poverty with an NTD in the United States,¹⁹ as well as the high rates of these diseases among the poor in areas such as Europe, Australia, and of course the large middle-income countries that comprise the Group of 20 such as Brazil, China, India, and Indonesia.

With the ending of the MDGs, a new set of 17 Sustainable Development Goals (SDGs) has been launched (Box 231.3). The SDGs include a goal for health that includes targets for universal coverage, but they also emphasize heavily the environment and calls to reduce carbon emissions to slow climate change and global warming. The new SDGs

FIG. 231.1 Millennium Developmental Goal 4 to reduce child mortality. (From World Health Organization. Child health. Available at: http://www.who.int/gho/child_health/en/index.html.)

BOX 231.3 Sustainable Development Goals

1. **No poverty:** End poverty in all its forms everywhere
2. **Zero hunger:** End hunger, achieve food security and improved nutrition, and promote sustainable agriculture
3. **Good health and well-being:** Ensure healthy lives, and promote well-being for all at all ages
4. **Quality education:** Ensure inclusive and equitable quality education, and promote lifelong learning opportunities for all
5. **Gender equality:** Achieve gender equality, and empower all women and girls³⁷
6. **Clean water and sanitation:** Ensure availability and sustainable management of water and sanitation for all
7. **Affordable and clean energy:** Ensure access to affordable, reliable, sustainable, and modern energy for all
8. **Decent work and economic growth:** Promote sustained, inclusive, and sustainable economic growth, full and productive employment, and decent work for all
9. **Industry, innovation, and infrastructure:** Build resilient infrastructure, promote inclusive and sustainable industrialization, and foster innovation
10. **Reduced inequalities:** Reduce income inequality within and among countries
11. **Sustainable cities and communities:** Make cities and human settlements inclusive, safe, resilient, and sustainable
12. **Responsible consumption and production:** Ensure sustainable consumption and production patterns
13. **Climate action:** Take urgent action to combat climate change and its impacts by regulating emissions and promoting developments in renewable energy
14. **Life below water:** Conserve and sustainably use the oceans, seas, and marine resources for sustainable development
15. **Life on land:** Protect, restore, and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss
16. **Peace, justice and strong institutions:** Promote peaceful and inclusive societies for sustainable development, provide access to justice for all, and build effective, accountable, and inclusive institutions at all levels
17. **Partnerships for the goals:** Strengthen the means of implementation, and revitalize the global partnership for sustainable development

From United Nations. Sustainable development goals. <http://www.un.org/sustainabledevelopment/sustainable-development-goals/>.

reflect a need for physicians and other health care providers to become broadly trained and consider interdisciplinary approaches to solving global health problems.

FUTURE DIRECTION OF GLOBAL HEALTH

The rise of noncommunicable diseases by no means implies any reduction in the importance of infectious diseases in the coming years. Indeed, quite the opposite. For instance, the catastrophic epidemic of Ebola virus infection in Guinea, Liberia, and Sierra Leone in 2014 to 2015 dramatically highlighted our global vulnerability to emerging and neglected diseases. Among the forces that promoted the spread of Ebola virus infection in West Africa were poverty and the collapse of health systems in those countries because of long-standing civil conflict and war, together with deforestation, urbanization, human migrations, and climate change.³ Today, these socioeconomic and environmental forces are not unique but are being replicated in several parts of the world, including the Middle East and North Africa, where we have seen the emergence or re-emergence of Middle Eastern respiratory syndrome coronavirus infection, leishmaniasis, and schistosomiasis, among other diseases.²⁰ A second and important alarming trend is the dramatic

increase in vector-borne diseases, especially the arbovirus infections. There has been an explosion of dengue fever cases, especially in India, Indonesia, Brazil, and elsewhere,³² as well as the emergence of chikungunya³¹ and Zika virus in Latin America. Southern Europe has also seen new and unprecedented cases of dengue, chikungunya, and West Nile virus infection. Pandemic influenza and related viral infections also remain of enormous concern, as does the threat of widespread emergence of antimicrobial drug resistance of gram-negative bacteria and *Mycobacterium tuberculosis*.

In response the US Government has initiated a Global Health Security Agenda in partnership with the major UN agencies committed to health and ministries of health of dozens of countries globally, whereas globally the WHO and other organization are looking to lessons learned from the 2014 to 2015 Ebola epidemic to revise and update policies, including the International Health Regulations, for streamlined global epidemic response capabilities.^{13,15,33} In parallel there is recognition that we need to identify mechanisms to accelerate the development of new countermeasures, including vaccines for many of the diseases highlighted earlier.²¹ Thus the future directions of global health include collaborative progress by medical and public health teams, industry, world leaders, governments, NGOs, and private nonprofit philanthropic organizations in the context of the new SDGs (Figs. 231.2 through 231.11).¹

In addition, future directions include advances in technology for diagnosis, treatment, and prevention of diseases of global importance; application of new technologies into global public health practice; education of new generations of global health scientists and global public health experts to develop and apply these new technologies to global health; and expansion of Internet and mobile applications to reach and educate people in developing world.²⁴

An example of a rapidly emerging development in diagnostics in the field is “lab-on-a-chip” (LOC) technology, which may soon become an important part of efforts to improve global health, particularly through development of point-of-care testing devices. In poorly equipped clinics in resource-poor countries, treatable infectious diseases soon may be accurately diagnosed by clinicians using immunoassays and nucleic acid assays performed by microfluidic LOC technology, thereby allowing appropriate treatments to be administered. For example, accurate diagnosis of HIV infection and measuring the number of CD⁺ T lymphocytes, with resultant antiretroviral treatment, may soon be possible with LOC brought to resource-poor areas where most of the untested, untreated HIV-infected individuals reside.^{9,38} For the chips to be used in areas with limited resources, many challenges must be overcome. In developed nations, the most highly valued traits for diagnostic tools include speed, sensitivity, and specificity, but in countries where the health care infrastructure is less well developed, attributes such as ease of use and shelf life must also be considered. If LOCs are to be used in the resource-poor areas of the developing world, their reagents must have a long shelf life at tropical room temperatures, as well as have low cost, scalability, and recyclability.

Trainees in undergraduate and postgraduate courses in public health, medical schools, and medical residencies and fellowships, as well as students in schools of nursing and physician assistant training, have a growing interest in understanding the major factors that influence global health of individuals and populations worldwide.^{39–42} Most medical schools and public health institutions are developing global health essential core competencies to provide their students with basic understanding of the complexity of global health issues, especially in low-resource settings, and the control of diseases of importance to global health.^{10,39} In addition to studies in the classroom, many institutions now provide practical experience in international settings and global health career path training (Fig. 231.12).⁴² A National School of Tropical Medicine was established in 2012 in Houston, Texas, thus providing a North American counterpart to the century-old Liverpool School of Tropical Medicine and the London School of Hygiene and Tropical Medicine.¹⁷ The future of communication and information technology also includes global health. Social media provide unprecedented connectivity because even in the most resource-poor areas of the world, fragmented levels of power and Internet access are available (Fig. 231.13).⁴⁶ Social media are being used by philanthropic

FIG. 231.2 (A) River scene near the rural town of Doma, Nasarawa State, Nigeria showing men, women, and children using river water for washing. The river also may be used to wash motorcycles and cars and even for drinking. Providing access for the world's people to safe and clean water for drinking and washing is one of the Millennium Developmental Goals for 2015. (B) Orphan girl at the Kang'oma orphanage and day care center near Mzuzu, Malawi takes a drink from a new water well and hand pump built by United Nations volunteers in August 2012. The well provides access to clean water for drinking and washing and helps prevent diarrheal diseases, dehydration, trachoma, and other diseases. Malawi is one of the poorest host countries in the "bottom billion." To halve the number of people without access to clean water and sanitation is one of the Millennium Development Goals to be achieved by 2015. (A, Courtesy Dr. Gail J. Harrison. B, Courtesy Byron McCord and Holly McBride.)

FIG. 231.3 Children gathered in front of the medical and surgical cottage hospital in Doma, Nasarawa State, Nigeria. Many children are shown with water, melons, and cashews in baskets balanced on their head, which they sell to local people through street trading or hawking. This practice is common in Nigeria; although it allows a means to make an income for their family's survival, it also often keeps the children from attending school and receiving an education, thereby perpetuating the cycle of poverty. To achieve universal primary education is one of the Millennium Development Goals for 2015. (Courtesy Dr. Gail J. Harrison.)

FIG. 231.4 Surgical procedures performed in remote areas of the world often must be done under stark and challenging conditions. This 3-year-old boy from Doma, Nasarawa State, Nigeria is having a right inguinal herniorrhaphy performed, under ketamine anesthesia, by local physicians in an operating room in Doma Hospital, Nasarawa State, Nigeria. The procedure was successfully completed, he awakened, and he received a postoperative intramuscular injection of an antibiotic to prevent infection. (Courtesy Dr. Gail J. Harrison.)

FIG. 231.5 The evaluation and treatment of patients for infectious diseases in remote rural areas are challenging efforts because microbiologic cultures, laboratory tests, diagnostic imaging, biopsies, and intravenous infusions are not available. In this photograph, the clinician, using natural light provided through a window, explains the findings of a plain radiograph showing destructive bone changes of the proximal right femur, consistent with chronic osteomyelitis. The patient, an 11-year-old boy, had a 2-year history of painful limp, chronic draining fistulous tracts, and tenderness over the proximal femur. Lack of money and access to transportation precluded accessing medical care with specialists in an urban hospital. The child was provided with crutches to help ease pain and facilitate mobility, as well as a 3-month supply of oral antibiotics. He also was given a “written referral” to a specialist in the medical center in Abuja, Nigeria, but unless he is able to travel to the larger urban center, his next follow-up will be in 1 to 2 years at the next medical mission. (Courtesy Dr. Gail J. Harrison.)

FIG. 231.6 Medical wards in hospitals in remote, resource-poor, rural areas of the “bottom billion” countries are often stark, are maintained as well as possible with available resources, and lack modern equipment to which health care providers in resource-rich countries are accustomed. (Courtesy Dr. Gail J. Harrison.)

FIG. 231.7 This 13-year-old Nigerian girl had a several-year history of increasing kyphosis. A soft, nontender mass was palpated along her spine. The presumptive diagnosis was Potts disease, a presentation of extrapulmonary tuberculosis that most commonly affects the lower thoracic and upper lumbar vertebrae of the spine. The sixth goal “to combat HIV/AIDS, malaria, and other diseases” of the Millennium Development Goals specifically addresses the health and economic impact of infectious diseases on global health. It includes programs specifically targeted to combat tuberculosis.⁴³ (Courtesy Dr. Gail J. Harrison.)

FIG. 231.8 Street scene with market and plantains, also called “cooking bananas,” laid out for sale in Katende, in the Mpigi District, Uganda. Uganda is a developing country with more than 41 million people that is located on the Equator in East Africa. It is experiencing fast population growth, and most crops are still cultivated and produced by local farmers and sold in local markets. The common cultivated crops in Uganda include maize, cassava, yams, and sweet potato, which are all high-carbohydrate-content foods, and groundnuts and beans, which are high in protein and eaten to complement the starch crops. Meat or fish protein is a rare luxury. The high-carbohydrate diet consumed on a daily basis is contributing to a rising prevalence of type 2 diabetes mellitus in the adult population of Uganda. Millennium Development Goal 1 called to end or reduce extreme poverty and hunger. Sustainable Development Goal 2 or Zero Hunger calls to end hunger and achieve food security and improved nutrition and promote sustainable agriculture. (Courtesy Dr. Gail J. Harrison.)

FIG. 231.9 Market street scene, outside of Kampala, in the Mpigi District, Uganda, with many people traveling on foot. Also notice the motorcycles, which are a common mode of transportation in Uganda, and the delivery truck. The motorcycles may be used for personal transportation for families that can afford to own their own, or as motorcycle taxis or “boda boda” for public transportation. Increasing population in Uganda has led to an increasing demand for public transportation. “Boda boda” provide an affordable means of public transportation and also vital job opportunities for entrepreneurial young men. They are also a frequent cause of road accidents, injuries, and death. In addition, the rapid urbanization and economic growth of cities in Uganda have given rise to air pollution, which is one of the biggest challenges faced in urban centers of developing countries. The main cause of air pollution is transportation exhaust fumes. The effects of this pollution on people is now becoming evident, with rising incidences of chronic lung diseases such as asthma, chronic obstructive pulmonary disease, and lung cancer. It has been estimated that 14% of children between 8 and 14 years of age who are living in Kampala have asthma. Millennium Development Goal 7 called to ensure environmental sustainability and to integrate the principles of sustainable development into country policy programs and reverse the loss of environmental resources. The new Sustainable Development Goal 13 is Climate Action. It calls to take urgent care to combat climate change and its impacts by regulating emissions and promoting development of renewable energy. (Courtesy Dr. Gail J. Harrison.)

FIG. 231.10 A public toilet in the area of Kampala, in the Mpigi district of Uganda in East Africa. It is estimated less than 20% of the population in Uganda has access to toilets that are not shared and that are made with improved sanitation mechanisms that separate waste from human contact. Public sewer systems with water-borne flush toilets are still rare in Uganda and are present only in the wealthy residential and business districts. Open urination and defecation, or elimination into plastic or polythene bags (“flying toilets”), which are disposed of by throwing the bags into drainage channels, are sometimes the only options for the resource-poor areas. More fortunate areas may have public toilets, “outhouses,” or pit latrines. These public toilets often overflow, and in the rainy season, sewage runs into the water-trapping gullies in the town, thus providing a source of disease such as typhoid and cholera. Women and girls often do not use public toilets, or do so in groups, because they often experience humiliation and have been victims of violent crimes such as assault and rape. Millennium Development Goal 7 called to ensure environmental sustainability and to halve the proportion of the population without sustained access to safe drinking water and basic sanitation. The new Sustainable Development Goal 6 calls for clean water and sanitation to ensure availability and sustainable management of water and sanitation for all. (Courtesy Dr. Gail J. Harrison.)

FIG. 231.11 Ugandan children. Millennium Development Goal 2 called for primary education allowing all children regardless of gender to complete a full course of primary education schooling and to promote gender equality and empower women and eliminate gender disparities in primary and secondary education. Sustainable Development Goal 4 calls for quality education to ensure inclusive and equitable quality education and promote lifelong learning opportunities for all. (A) These children came to the medical mission camp set up in a field near Katende, Uganda. All were fit and healthy appearing, except notice the boy on the left with a facial palsy of unknown cause. These children were “out of school.” Education is a human right for all children, yet many children in resource-poor areas of the world do not receive an education. Even though Uganda is one of the first African countries to introduce universal primary education (both government and private schools), many children have never enrolled in school (“nonenrolled children”) or drop out of primary school (“out of school” children). These children are often socially and economically disadvantaged, and their parents cannot afford the costs of scholastic materials such as pens, books, or a school lunch or uniform. Many children drop out of school to help support their family financially. Moreover, when girls start their menstrual period, they often drop out of school because they lack access to sanitary pads and other personal hygiene supplies. (B) and (C), These children are from St John’s Bosco Katende Primary School located in Katende, about 15 miles from Kampala, Mpigi District, Uganda. It is a government-sponsored local primary school. The students participated in group tennis instruction as part of the “A Court Everywhere” (ACE) outreach program, sponsored by Neil Harrison Serves Tennis. A tennis court was fashioned from local resources: the clay dirt in the open field formed the court base, and tennis lines were made from ashes from the local open fire kitchens. Seven years of primary school (government or private) are provided in the education system in Uganda, from grades 1 to 7 (ages 7 to 13 years). On completion of their first 7 years, students must pass their “Leaving Exams” to continue to the next level of secondary education. (D) These children are from a local private secondary school near Kampala, Uganda. They participated in group tennis instruction as part of the ACE outreach program. Four years of secondary school (government or private) for middle-level education is provided in the education system in Uganda, from ages 14 to 17 years. Following the British model of education, Ugandan students who pass their O-Level examinations may proceed to Upper Secondary, advanced-level education. If students continue to be successful in school, and pass their A-Level examinations, they may attend Tertiary Education Universities at 1 of the 5 state universities, 11 religious-affiliated universities, or 1 private secular university in Uganda. For those students who do not perform well on their examinations, they may still attend technical colleges. (Courtesy Dr. Gail J. Harrison.)

FIG. 231.12 Dr. Gelane Workneh (left) works with residents and medical students as she makes rounds in the pediatric ward at University of Gondar Hospital (October 11, 2011) in Ethiopia. Dr. Workneh is one of three doctors the Texas Children's Hospital Global Health Corps physicians and the Baylor College of Medicine Pediatric AIDS Initiative provide to work with the Jewish Joint Distribution Committee and Gondar University College of Health Sciences in Gondar as part of a 3-year grant. These doctors work to expand pediatric medical capacity in Ethiopia by teaching medical students and interns from Gondar University and by training local health care professionals. Global health experiences have become an important part of medical education curriculum in many major medical centers. (Courtesy Smiley N. Pool and Baylor International Pediatric AIDS initiative, Houston, Texas.)

FIG. 231.13 Internet access through personal computers, local Internet cafes, and handheld mobile devices has reached even the most remote areas of the world and provides creative opportunities to improve global health and awareness in these remote communities. (Courtesy Dr. Gail J. Harrison.)

organizations, such as the Bill & Melinda Gates Foundation, to update their donors and partners on measurable markers of progress toward defined global health goals.³⁰ Mobile global health education applications, linking smart phones and pico projectors and other mobile technology, have the potential to be inexpensive, sustainable, ubiquitous, acceptable, and therefore effective in disseminating information on a global scale and linking resource-rich areas with remote, resource-poor areas of the

world. In addition, mobile devices may be used for surveillance⁴⁴ of infectious diseases, as well as chronic conditions such as heart disease, hypertension, and diabetes. Mobile devices also may be used for global health surveys and health information systems management. Mobile technology is also ideal for providing rapid scientific, epidemiologic, and public health knowledge at the time of a disaster. Mobile technologies may soon revolutionize global health care because individuals who are patients in resource-poor remote areas also may own or borrow mobile phones, thereby allowing communication to access health care when needed and reducing mortality.⁴⁵ As an example of creative adaptability, in “light-poor” communities and villages without reliable electrical power at night, the light provided by individual cell phones allows health care providers to assist in medical procedures, including deliveries of babies at night.⁴⁶

Nicholas Weinberg • Susan A. Maloney

During the past half-century, the number of persons traveling internationally has increased tremendously. Between 1980 and 2011, the number of international arrivals worldwide more than tripled, growing from 277 million to 983 million. In 2015, US residents took more than 32 million trips overseas, 28 million trips to Mexico, and 12.5 million trips to Canada. Among the overseas US resident travelers, 12.5 million (17%) visited Europe, 10.4 million (10%) visited the Caribbean, 6.6 million (6.6%) visited Asia, 4.6 million (6.3%) visited Central and South America, 2 million (2.8%) visited the Middle East, 350,000 (0.5%) visited Africa, and 640,000 (0.9%) visited Oceania.^{161,162,181} Although the exact number of children traveling is unknown, 2.2 million US travelers (8%) were adults and children traveling together and 3.1 million (11%) reported their occupation as students.¹⁶⁰ Worldwide, Mexico and Asia were the fastest growing destinations in terms of international tourist arrivals, with each growing more than 6% in 2015.

Study abroad by since the 1990s in the last 20 years; more than 289,000 US students studied abroad during the 2013 to 2014 school year. The United Kingdom, Italy, Spain, France, and China were the top host destinations; however, the numbers of students studying in Mexico, Chile, and Greece each increased by double digits.¹⁰²

International travelers may be exposed to a variety of health risks, depending on the travel destination, trip itinerary, duration of stay, planned travel activities (i.e., business vs. adventure), individual risk factors, and preventive measures taken. For persons from industrialized countries visiting developing countries, travel may expose them to a variety of infectious pathogens and environmental hazards, some of which they may rarely encounter at home. Other infectious agents (e.g., chikungunya) may present a potential threat to public health by extending their presence into the United States.¹³⁵ Despite the well-documented health risks associated with international travel, surveys have shown that many travelers do not seek pretravel health advice or obtain appropriate travel-related preventive medications or vaccinations. As a result of global patterns of human migration, children are increasingly likely to accompany their parents on trips to lower income destinations, particularly to visit friends and family. Children have been repeatedly shown to be more vulnerable to preventable outcomes. Evaluation of data reported to the GeoSentinel Surveillance Network between 1997 and 2007 revealed that compared with adults, children disproportionately presented for medical care within 7 days of return, required hospitalization, lacked pretravel health advice, and had traveled for the purpose of visiting friends and family.⁹⁰ Surveys of US, European, and Australian travelers have shown that only 31% to 52.1% of the travelers sought travel advice before the trip. In an airport survey of 203 US passengers traveling to high-risk, malaria-endemic areas, only 46% were carrying antimalarial medications with them,^{91,165,173} and few were vaccinated for their travel—only 11% for tetanus, 14% for hepatitis A, 13% for hepatitis B, and 5% for yellow fever.⁹¹ Among 1704 respondents from the 2008 YouthStyles survey, an annual mail survey of demographics and health knowledge, attitudes, and practices of youth age 9 to 18 years, 131 (7.7%) traveled in the past 12 months; of these travelers, only 16.7% reported seeking pretravel medical care, mostly (84%) from a family doctor.⁹² In a survey of 318 American students studying abroad, the primary source of travel health information was reported to be youth-oriented travel guidebooks (85%).⁹³

TRAVELERS VISITING RELATIVES AND FAMILY

Travelers who are visiting friends and relatives are at high risk for acquiring a variety of illnesses, are more likely to travel for longer periods

of time, and are less likely to seek pretravel medical advice.^{10,11,15,37,116} A review of 3332 children seeking care through the Global TravEpiNet between 2009 and 2012 showed that children visiting relatives and family tend to be younger when they travel and are more likely to have a travel-related visit less than 14 days before departure.^{88,116} In another study of children visiting families and relatives who required medical care after travel, only 33% to 50% had received pretravel advice.⁹⁰ Systemic febrile illnesses (including malaria), nondiarrheal intestinal parasitic infections, respiratory syndromes, tuberculosis, and sexually transmitted infections (STIs) were more commonly diagnosed among immigrants visiting friends and relatives than in other travelers, whereas acute diarrhea was less frequent. In contrast to other travelers, the immigrants who were visiting friends and relatives were more likely to travel to sub-Saharan Africa or Latin America and to take a trip lasting longer than 30 days.¹¹⁶ In a review of travelers presenting at one GeoSentinel Surveillance Network clinic site, the proportion of travelers with malaria who had been visiting friends and relatives was eight times greater than among tourists (16.9% vs. 2.1%).¹¹⁴

Compared with adults, children are more likely to have illness after visiting relatives.⁹⁰ Given that children tend to be the least likely to seek care and the most likely to become ill, every effort must be made to encourage this particularly vulnerable group of travelers to receive appropriate care. Reasons for lack of care are likely multifactorial and include lack of access to care because of barriers at the health system level as well as lack of perception of risk.^{11,15} Possible ways to encourage travelers to receive preventative services include asking parents during regular well-child care visits about any future planned travels; encouraging insurance companies to fully cover the cost of travel vaccines and travel-related medications, including malaria prophylaxis; and improving access to care for immigrant families.^{114,116}

PEDIATRIC TRAVELERS AND HEALTH RISKS ABROAD

Recent studies have identified several major categories of morbidity among pediatric travelers: diarrheal illnesses, respiratory diseases, dermatologic conditions, and systemic febrile illnesses. In a multicenter study evaluating the morbidities of 1561 children returning from 218 global destinations presenting after travel, Hagmann and colleagues found that diarrheal syndromes were most common (28%), followed by dermatologic conditions (25%), systemic febrile illnesses (23%), and respiratory disorders (11%).⁹⁰ Dermatological conditions were twice as common after exposure to Latin America, and travel to the Middle East or North Africa was associated with greater risk for diarrheal disorder.⁹⁰ Herbing and colleagues⁹⁵ reviewed data from 890 children younger than 20 years at an outpatient travel clinic at the University of Munich, Germany after travel to Africa (46%), Asia (35%), and Latin America (19%). The most frequent syndromes were acute diarrhea (25%, especially in children 0–4 years of age), dermatologic conditions (19%, especially in children 0–9 years of age), febrile and systemic diseases (20%), respiratory disorders (8%), chronic diarrhea (5%), and genitourinary disorders (3%). The 10 most frequently diagnosed infectious diseases were giardiasis (8%), schistosomiasis (4%), superinfected insect bites (4%), *Campylobacter* enteritis (4%), *Salmonella* enteritis (4%), cutaneous larva migrans (3%), amebiasis (3%), dengue fever (2%), mononucleosis (2%), and malaria (2%).⁸² Hunziker and colleagues⁹⁸ reviewed data from 328 children 16 years and younger with travel-associated illness at the emergency department of the University of Zürich Children's Hospital. The main conditions were diarrheal illness

(39%), respiratory illness (28.7%), and systemic febrile illness (13.4%). No deaths were reported. Among 36 children with more serious diseases requiring hospitalization, 12 (3.7% overall) had potentially serious diseases: malaria ($n = 2$), *Salmonella typhi* ($n = 3$), *Salmonella paratyphi* ($n = 2$), meningococcal meningitis ($n = 1$), tuberculosis ($n = 2$), visceral leishmania ($n = 1$), and hepatitis A ($n = 1$). Eleven of the 12 children with serious diseases were visiting friends and family or immigrant children.⁹⁸ Van Rijn and colleagues¹⁶⁶ conducted a prospective observational cohort study of 152 children and their parents traveling to the tropics and subtropics; 85% of all children reported some kind of ailment during travel, with a mean ailment rate of 7 ailments per person-month of travel. The most frequently reported ailments were skin problems, including insect bites, sunburn, and diarrhea.¹⁶⁶

Other authors have reported substantial health risks for pediatric travelers from noninfectious causes such as injuries. Most deaths are associated with swimming or automobile accidents.^{97,118} One study of British children drowning abroad while traveling showed that an average of eight British children drown each year abroad, primarily in swimming pools without adequate lifeguards.⁶⁹

Although some data from adult travelers can be extrapolated to use in the management of pediatric travelers, infants and children have special vulnerabilities and needs when preparing for travel abroad. These needs include (1) up-to-date and appropriate vaccinations (at times through accelerated or altered routine childhood vaccine schedules and also including special travel-related vaccines); (2) appropriate malaria and other chemoprophylaxis regimens tailored for use in pediatric travelers; (3) prevention counseling, particularly in the areas of food and water safety, insect barriers, and injury prevention; and (4) anticipatory guidance for the management of potential illness and successful location of medical resources overseas. This chapter provides recommendations for conducting a pediatric pretravel assessment to ensure that the child has received the appropriate vaccination and chemoprophylaxis regimens, pretravel prevention counseling, and means of accessing additional sources of travel information about health risks and the availability of medical resources at specific travel destinations.

GENERAL APPROACH TO PRETRAVEL ASSESSMENT FOR CHILDREN

Before embarking on international travel, children should have a pretravel health assessment performed by a health care provider. The number of physicians who specialize in travel medicine for children is relatively limited, and many pretravel assessments are performed by general pediatricians, pediatricians who specialize in infectious diseases, or travel medicine specialists without specific pediatric training. A study performed by members of the International Society of Travel Medicine (ISTM) Pediatric Interest Group found that even doctors who professed an interest in travel medicine often did not follow appropriate travel guidelines to prevent travel-associated morbidities in pediatric travelers.⁸⁹ Hence there need to be renewed attempts to train even those self-declared health professionals interested in travel medicine in order to prevent travel-related illnesses. Depending on the destination and the vaccinations recommended or required, the assessment should be conducted optimally 6 to 8 weeks before travel. Because families may not be aware of the need for multiple vaccinations and medications, health care providers should be proactive and routinely ask patients and their families if they are anticipating any international travel in the next several months, especially before holiday periods.

During the pretravel assessment, the provider should do the following:

1. Review the child's current and past medical history, including the status of routine childhood vaccinations.
2. Obtain specific details about the travel itinerary and planned activities. Review endemic diseases and recent outbreaks in travel destinations.
3. Administer indicated routine and travel-related vaccinations.
4. Prescribe antimalarial, other prophylactic, or self-treatment medication (based on risk assessment from the medical history, travel itinerary, and planned activities).
5. Counsel about prevention of travel-related illnesses, especially focusing on infectious diarrhea and mosquito-borne illnesses.

6. Provide guidance about seeking medical assistance for travel-related illness.

The pretravel assessment should include a detailed review of the trip itinerary. On the basis of risk assessment, preventive health counseling should include information about food and water safety, prevention of vector-borne illnesses, and other infectious and noninfectious illnesses, such as STIs and automobile accidents. General and specific prevention counseling recommendations are addressed later in the chapter. In addition, families should clarify with their health insurance company whether they are covered for health care provided abroad. If not, insurance can be purchased from several companies; such insurance may include coverage for health care providers in a specific country and airlift medical evacuation. If assistance for illness acquired abroad is needed, the US embassy or consulate can provide names and addresses of English-speaking health care providers at the travel destination. This information can be obtained before departure by accessing embassy Internet sites or by calling the embassy. In addition, names of physicians abroad can be obtained from some worldwide directories (see the discussion on international travel information resources). Parents should be told to carry all health-related documents with them for easy retrieval, including written prescriptions for medications, health insurance information, and medical contacts abroad. Counseling on ensuring the use of sterile needles and the safety of the local blood supply also should be included in pretravel prevention counseling topics; blood screening and infection control practices may not be as stringent in some countries as in the United States.

Special consideration must be given to children who have chronic diseases. Children with medical conditions should take a summary of their medical history and treatment record. If the child has cardiac disease, the family should consider taking a copy of the child's recent electrocardiogram and echocardiography report. Children with diabetes who are traveling through more than one time zone should consult their pediatrician or endocrinologist for guidance on the need for altering insulin dosing. Prescription medications should be carried in original bottles, and a sufficient supply for the length of the planned trip and a few extra doses should be packed. Required medications should be carried on the plane rather than packed in luggage because bags may be lost or exposed to unfavorable environmental conditions. Families should be counseled about the potential hazards of obtaining medications in pharmacies in developing countries, where many medications can be purchased over-the-counter without a prescription and where the names, content, and concentration of medications may be different from those of US products. Parents carrying medical equipment (such as nebulizers) should remember to take adaptors for foreign electric current and bring a letter from a physician that documents the need for the equipment.³⁶ Similar documentation is encouraged for anaphylaxis kits or other medications that require syringes.

VACCINATION FOR INTERNATIONAL TRAVEL

The provider should consider three categories of vaccinations: routine childhood vaccinations, required travel-related vaccinations, and recommended travel-related vaccinations. Some routine vaccinations should be administered at an earlier age or after an accelerated schedule in preparation for international travel. In addition, the provider should review and administer travel-related vaccinations that are required for entry by various countries to prevent the importation of disease and development of outbreaks, as well as vaccinations recommended for the prevention of illness in the individual traveler.⁴¹ Currently, only two vaccines—yellow fever and meningococcal—are required for entry by selected countries; however, these requirements may change in the future. Vaccination recommendations change rapidly. Whereas this section provides guidance as of publication date, clinicians should obtain the most current recommendations available on the Centers for Disease Control and Prevention (CDC) website (see the discussion on international travel information resources).

Routine Childhood Vaccinations for Pediatric Travelers

For children who will be traveling internationally, having their routine immunizations brought up to date is essential because many vaccine-preventable diseases are more prevalent in countries outside the United

States. In particular, children who have nonmedical exemptions to routine vaccinations may be at high risk for acquiring vaccine-preventable diseases, such as measles and rubella, that no longer are endemic in the United States but still occur frequently in other countries, including many European destinations. The pretravel visit also may give the health care provider a unique opportunity to update the routine vaccination status of a patient who has fallen behind schedule. In certain cases, routine vaccinations may need to be accelerated to maximize protection, particularly against polio, diphtheria-tetanus-pertussis, varicella, hepatitis A, hepatitis B, and measles (e.g., measles vaccination is recommended for children 6–11 months of age).^{7,113} Many vaccine series can be initiated as early as 6 weeks of age. The management plan for routine vaccinations will be determined by the travel destination and itinerary. For example, diphtheria and pertussis are prevalent in Eastern Europe and many developing countries, and measles is still endemic in the developing world and some European countries; therefore, if travel to these countries is planned, ensuring immunity is imperative, and accelerated schedules should be considered. In addition, parents should check their own immune status because traveling with children can increase their risk for exposure to measles and other vaccine-preventable diseases.^{99,100}

Measles

Measles was declared eliminated in the United States in 2000. However, travelers to Europe, Asia, the Pacific, and Africa continue to be at risk. High two-dose mumps, measles, and rubella (MMR) vaccine coverage is essential for travelers to prevent measles importation and outbreaks in the United States. In 2014, the United States experienced a record number of measles cases, with 667 cases reported from 27 states. One large multistate outbreak involved Disneyland Parks and likely started from a traveler who became infected overseas because the measles virus type (B3) was identical to the virus type that caused an outbreak in the Philippines in 2014. In this widely publicized outbreak, at least 125 US citizens were diagnosed with measles between December 2014 and February 2015, with 110 cases in California alone. Thirty-nine (35%) of the Californians infected visited Disneyland parks during December 17 to 20, 34 (31%) were secondary cases, and 37 (34%) had an unknown exposure source. Most of the secondary cases were household contacts. Forty-nine affected individuals (45%) were unvaccinated, 5 (5%) had one dose of measles-containing vaccine, seven (6%) had two doses, 1 (1%) had three doses, and 47 (43%) had unknown or undocumented vaccination status.^{51,182} Similarly, measles outbreaks in 2011 were associated with travelers returning from overseas, with most cases occurring in undervaccinated or unvaccinated individuals.⁴⁴ Numerous cases of serologically confirmed measles also have occurred among internationally adopted children and their new parents and siblings who had traveled to China to accompany them home. Data suggest that the exposure to measles occurred in China, probably at the orphanage, where an outbreak of measles was occurring.^{33,34}

The MMR vaccine is administered routinely to children starting at 12 months of age. However, the MMR vaccine should be administered to children 6 to 11 months of age who are traveling internationally. These children should be revaccinated with two doses of MMR vaccine—the first at ages 12 through 15 months and at least 4 weeks after the previous dose and the second at ages 4 through 6 years. Children older than 12 months of age who are traveling internationally should receive the second dose, as long as 4 weeks have passed since the previous dose; even if administered before 4 years of age, this second dose counts toward the routine vaccination and does not need to be repeated at a later age. Providers should remind their patients who plan to travel internationally of the increased risk for measles and potential exposures during bus, train, or air travel and at large international events or gatherings.

Hepatitis A

Hepatitis A is endemic in most of the world, and travelers are at risk in any area where sanitation is poor. In 2006, hepatitis A vaccination became part of routine childhood recommendations in the United States for all children at 1 year of age (12–23 months), supplementing recommendations in 1999 for vaccination of children 2 to 18 years of age residing in states and communities with high incidence of disease and

other high-risk groups. In addition, hepatitis A vaccine is now routinely recommended for all previously unvaccinated children aged 24 months or older for whom immunity is desired. Vaccination is recommended for pediatric travelers 1 year or older who will be visiting countries with intermediate to high endemicity, such as in Mexico, Central and South America, Asia, Africa, and eastern Europe.^{3,36,45} Hepatitis A vaccine is administered as a two-dose series. The first dose of hepatitis A vaccine should be administered at least 14 days before travel. Limited data are available about the timing of the appearance of neutralizing antibody. Among a sample of vaccinated persons, 54% to 62% were positive for neutralizing antibody 14 days after the first dose, and 94% to 100% were positive at 1 month.³ The second dose can be administered 6 months after the first dose. Intramuscular immunoglobulin is recommended for immunoprophylaxis against hepatitis A in children younger than 1 year. In addition, for children 1 year or older who will be departing sooner than 2 weeks after the pretravel visit (and therefore may not have sufficient time for immunity to develop after hepatitis A vaccination), both immunoglobulin and vaccine can be given concurrently at different sites to ensure more immediate protection. Shortages of immunoglobulin have occurred in the past, so obtaining it for hepatitis A prophylaxis may be difficult.⁴⁵ Hepatitis A outbreaks also have occurred among adoptees and their contacts, leading to American Academy of Pediatrics and the Advisory Committee on Immunization Practices recommendations for hepatitis A vaccination for all household members and close contacts, including babysitters, when children are adopted from countries with high or intermediate rates of hepatitis A infection. All nonimmune, unvaccinated people who will have close exposure to international adoptees during the 60 days after their arrival (regardless of whether they travel) should receive hepatitis A immunization, ideally 2 or more weeks before arrival of the adopted child.^{2,9}

Polio

Worldwide polio eradication efforts have decreased the number of countries where travelers are at risk for acquiring polio. In 2015, 74 cases of wild poliovirus were reported, representing a decrease of 99% from 1988, when the Global Polio Eradication Initiative was launched. Wild poliovirus is considered endemic in two countries: Afghanistan and Pakistan. Of the three strains of wild poliovirus (1, 2, and 3), wild poliovirus type 2 was eradicated in 1999 and the last case of wild poliovirus 3 was reported in Nigeria in 2012.¹⁸³ To ensure protection, pediatric travelers visiting countries where polio is epidemic or still endemic should be fully immunized, and young adults 18 years or older should receive one booster dose of inactivated polio vaccine (IPV) if traveling to areas with risk for transmission. Clinicians should obtain up-to-date information about areas of transmission from the World Health Organization (WHO) or CDC (see discussion on international travel information resources).

Influenza

Respiratory tract infections caused by influenza are a major cause of illness among travelers.¹¹⁵ Influenza can occur throughout the year in tropical countries. Peak influenza rates in temperate regions of the Southern Hemisphere occur from April through September. In North America, influenza vaccine may not be available during the summer months. All children 6 months and older should have routine influenza vaccination annually. Travelers to the Southern Hemisphere should be vaccinated by the spring, if possible. Influenza vaccinations should be considered for travelers who are at high risk for complications from influenza for travel to (1) the tropics any time of year, (2) the Southern Hemisphere from April through September, (3) any destination with large groups of tourists at any time of year, or (4) any destination where influenza outbreaks are occurring.³ In 2009, pandemic H1N1 outbreak emerged in Mexico and spread quickly around the world through travel. Protection against H1N1 is included in seasonal influenza vaccine.^{39,40}

Neisseria meningitis

Meningococcal disease occurs sporadically worldwide. Epidemic disease has been reported in India, Saudi Arabia, and sub-Saharan Africa; indeed, recurrent epidemics of meningococcal disease occur in sub-Saharan Africa, mainly from December to June (the dry season). Serogroup A

is the most common cause of epidemics outside the United States, but serogroup C and other serogroups also have been associated with epidemics. Serogroup W-135 meningococcal infection has been reported in travelers returning from Saudi Arabia after visiting the Hajj.¹⁶¹ Three meningococcal vaccines, a polysaccharide vaccine (MPSV4) and two conjugate vaccines (MCV4-D and MCV4-CRM), are available in the United States. Both conjugate vaccines are quadrivalent and effective against serogroups A, C, Y, and W-135. MCV4-D is licensed for use in children starting at 9 months of age, and MCV4-CRM can be used for children starting at 2 months of age. MCV4 (either MCV4-D or MCV4-CRM) is recommended for routine childhood vaccination in the United States for (1) all children at the 11- to 12-year-old visit, with a booster at 16 years of age; and (2) unvaccinated adolescents at 13 through 18 years of age, with a booster at 16 through 18 years. For infants aged 8 weeks to 6 months with functional/anatomic asplenia or complement deficiency, MCV-CRM can be given at 2, 4, 6, and 12 months. For infants and children 7 to 23 months old, MCV-CRM can be given in two doses administered at least 3 months apart, with the second dose given after 12 months. For children older than 2 months with functional/anatomic asplenia, complement deficiency, or HIV, either MCV-CRM or MCV4-D can be administered as a two-dose series given 2 months apart.¹⁴⁸ Meningococcal vaccination is recommended for pediatric travelers age 2 months or older who are visiting sub-Saharan Africa during the dry season or any country that is hyperendemic or where an epidemic caused by a vaccine serogroup is occurring using the above schedule. For children traveling to areas with risk for transmission, revaccination with MCV4 is recommended after 3 years for children who were previously vaccinated at 2 months to 6 years of age. Revaccination with MCV4 is recommended after 5 years for people who were previously vaccinated at 7 years or older and every 5 years thereafter for people who are at continued risk. Although it is less immunogenic than when it is administered to older children and adults, MPSV4 also can be used in children as young as 3 months to provide protection against serogroup A, such as travelers to areas with an epidemic or during seasonal transmission. These children should have two doses, 3 months apart.^{66,122,148} Furthermore, two US Food and Drug Administration (FDA)-approved vaccinations against serotype B, Trumenba and Bexsero, can be used in a two-dose series in children older than 10 years who are traveling to an area with an outbreak. Of note, they are used effectively in much younger populations in Europe.^{80,79}

Others Vaccine-Preventable Diseases

Hepatitis B, *Haemophilus influenzae* type b, rotavirus, *Streptococcus pneumoniae*, varicella, and human papillomavirus are endemic in many developing countries, and vaccination should be ensured.⁷⁰ For persons 18 years and older, a combination hepatitis A and hepatitis B vaccine (Twinrix) can be administered to travelers who need both vaccines. It is administered as a standard three-dose schedule at 0, 1, and 6 months after the first dose or can be accelerated at 0, 7, or 21 to 30 days, followed by a booster dose at 12 months.³⁸ Travel in large groups on conveyances such as cruise ships can facilitate the transmission of infectious and vaccine-preventable diseases.¹²⁴ The CDC has provided consultation on managing outbreaks of varicella and meningococcal disease in pediatric travelers on international cruise ships (CDC, unpublished data, 2013). For detailed information about accelerating routine childhood vaccinations and indications for use in pediatric travelers, see Table 232.1.

Common Travel-Related Vaccines for Children

An important consideration in determining travel vaccination needs is “required” versus “recommended” vaccinations. The most recent travel requirements and recommendations for vaccinations can be obtained from the CDC Travelers’ Health Internet site (see the discussion on international travel information resources). Currently, there are only two vaccines that are required for entry into a country; yellow fever and meningococcal vaccines. Many countries in South America and Africa may require proof of vaccination against yellow fever for entry, especially if the traveler is arriving from a country where yellow fever is present. Yellow fever vaccine is available only from certified yellow fever vaccination centers; providers can contact their state public health

department to locate certified centers in their areas. Saudi Arabia requires meningococcal vaccine for travelers visiting Mecca for the Hajj or for the Umrah.^{29,35,43} The United States does not require arriving travelers to have any vaccinations for entry or return to the United States. However, immigrants, refugees, asylum seekers, and internationally adopted children migrating to the United States for permanent residence have different requirements. Some countries previously have required cholera vaccination, but currently no countries require vaccination as a condition of entry.¹⁸⁰

Tables 232.1 and 232.2 provide general guidelines and indications for the use of routine and selected travel-related vaccines based on US recommendations.^{7,43,46,96,101,102,104} WHO recommendations may differ.¹⁸⁰ Depending on the complexity of the travel itinerary and the patient’s medical history, the vaccination plan may need to be developed in consultation with a travel medicine or infectious disease specialist. Travel-related vaccine recommendations should be tailored carefully to the trip itinerary and based on the travel destination, season when the travel will occur, duration of the trip, and activities to be undertaken.

Yellow Fever

Yellow fever occurs year-round in the predominantly rural areas of sub-Saharan Africa and South America; however, outbreaks have been increasing in incidence, particularly in Africa.¹⁵³ Infection occurs primarily through the bite of an infected mosquito, usually *Aedes* or *Haemagogus* spp. Transmission occurs in a human-to-vector-to-human cycle with monkeys, mosquitoes, and humans in three patterns: sylvatic (jungle), intermediate (savannah), and urban transmission. The resurgence of yellow fever in urban areas, in association with *Aedes aegypti* mosquitoes, has raised concern about increased risk in Brazil and urban areas of Latin America.^{43,167,168} Although a rare disease, yellow fever continues to be reported in travelers, particularly unvaccinated travelers, and is usually fatal. From 1970 through 2010, nine cases of yellow fever were reported in unvaccinated travelers from the United States and Europe who traveled to West Africa (five cases) or South America (four cases); eight (88%) of these travelers died. One case of yellow fever in a vaccinated traveler, who survived infection, has been reported.^{43,128} Preventive measures taken against yellow fever should include the use of personal protection against mosquitoes and vaccination. As discussed previously, some countries require yellow fever vaccination for travelers arriving from endemic regions; current requirements and recommendations for vaccination based on travel destination can be obtained from the CDC Travelers’ Health website.

Yellow fever vaccine is largely considered to be a safe and effective vaccine. However, the vaccine has been found to be associated with an increased risk for development of yellow fever vaccine-associated neurologic disease (YEL-AND), which includes meningoencephalitis, Guillain-Barré syndrome, and other severe reactions in young infants.⁷ The incidence is 0.8/100,000 doses. The vaccine should not be used in children younger than 6 months. It should be used with caution in children age 6 to 9 months after discussion with a travel medicine expert to weigh the risks and benefits.⁴³ Two cases of YEL-AND have been reported in children 6 to 8 months of age. Whenever possible, travel to yellow fever-endemic countries should be postponed for children younger than 9 months. Medical waivers can be given to children who are too young for vaccination and to those who have other contraindications to vaccination, such as immunodeficiency. Breastfeeding is a precaution for yellow fever vaccination. Three cases of transmission to infants have been associated with breastfeeding. None of the cases had permanent sequelae, but until more information is available, yellow fever vaccination should be avoided in breastfeeding women, if possible. Since 2001, yellow fever vaccine-associated viscerotropic disease (YEL-AVD), a life-threatening severe illness with major organ system failure similar to wild-type disease, has been reported in more than 50 confirmed and suspected cases worldwide. The syndrome usually consists of fever, jaundice, and multiple organ system failure. The case fatality ratio is 65%. The usual onset is 3 days (range, 1–8 days) after vaccination. The incidence of YEL-AVD cases in the United States is 0.4 per 100,000 doses of vaccine administered. The rate is higher in people 60 years

Text continued on p. 2297

TABLE 232.1 Routine Childhood Vaccinations and Accelerated Schedules and Modifications for Pediatric Travelers

Vaccine	Minimum Age	Routine Schedule ^a	Accelerated Schedule and Modifications ^b	Indications for Use and Other Information ^c
DTaP, DT	6 wk	5 doses at ages 2, 4, 6, 15–18 mo and 4–6 y	5 doses MI from dose 1 to dose 2: 4 wk MI from dose 2 to dose 3: 4 wk MI from dose 3 to dose 4: 6 mo Minimum age for dose 4: 12 mo MI from dose 4 to dose 5: 6 mo Minimum recommended age for dose 5: 4–6 y Dose 5 is not necessary if dose 4 was administered after the fourth birthday	Use for children ages 6 wk–7 y. Use DT for children age <7 y for primary series (instead of DTaP) when pertussis vaccination is contraindicated. The fourth dose may be administered as early as age 12 mo, provided at least 6 mo have elapsed since the third dose.
Tdap	10–11 y, depending on brand	One dose		Only 1 dose of Tdap is recommended. All subsequent doses of tetanus-diphtheria booster should be administered as Td. Tdap should be substituted for a single dose of Td in the catch-up series for children 7–10 y. If additional doses are needed, use Td. Tdap can be administered regardless of the interval since the last tetanus and diphtheria toxoid-containing vaccine.
Td	7 y	1 booster dose every 10 y Children ≥11 y should receive 1 dose of Tdap, followed by booster doses of Td every 10 y	MI for booster for travel: 5 y	Td should be used rather than Tdap if Tdap is not available and for: Anybody who has already received Tdap Additional doses for children 7–10 y in the catch-up series (one dose of Tdap should be administered) See information for Tdap regarding timing of Td vs. Tdap.
<i>Haemophilus influenzae</i> type b (Hib)	6 wk	4 doses at ages 2, 4, 6, and 12–15 mo or 3 doses at ages 2, 4, and 12–15 mo (PRP-OMP vaccines only) Unvaccinated child >15 mo: 1 dose	Accelerated schedule is available but varies by vaccine brand; see package insert for vaccine used MI between doses: 4–8 wk	MI between doses depends on age. Children receiving the first dose of vaccine at age ≥7 mo require fewer doses to complete the series. See <i>MMWR Morb Mortal Wkly Rep</i> 2005;54:Q1–4, for indications. Vaccinate all children <5 y and children >5 y with special indications (e.g., asplenia, immunodeficiency).
Hepatitis A	1 y	2 doses at ages 12 and 18 mo	MI from dose 1 to dose 2: 6 mo	Recommended for all children at 1 y (12–23 mo). Recommended for unvaccinated children ≥24 mo at high risk (see <i>MMWR Morb Mort Wkly Rep</i> 2006;55[RR-7]), and anyone ≥24 mo, previously unvaccinated, for whom immunity against hepatitis A virus infection is desired. Recommended for all persons ≥12 mo traveling to endemic areas, including Mexico, Central and South America, Asia (except Japan), Africa, and eastern Europe. ^d Immunogenicity: limited data are available for the timing of the appearance of neutralizing antibody. Among a sample of vaccinated persons, 54–62% were positive for neutralizing antibody 14 days after the first dose, and 94–100% were positive at 1 mo. ^e

Continued

TABLE 232.1 Routine Childhood Vaccinations and Accelerated Schedules and Modifications for Pediatric Travelers—cont'd

Vaccine	Minimum Age	Routine Schedule ^a	Accelerated Schedule and Modifications ^b	Indications for Use and Other Information ^c
Hepatitis B ^e	Birth	3 doses at 0–2, 1–4, 6–18 mo For children not previously vaccinated: 3 doses at 0-, 1-, and 4-mo intervals For unvaccinated adolescents 11–15 y: 2-dose vaccine series (only Recombivax HB, adult dose) at 0, 4–6 mo or 3 doses of other vaccine brands	3 doses (except 2 doses of Recombivax HB, adult dose for adolescents) MI from dose 1 to dose 2: 4 wk MI from dose 2 to dose 3: 8 wk MI from dose 1 to dose 3: 16 wk Minimum age for dose 3: 6 mo	Use for travelers to endemic areas, including Africa, Asia, Latin America, who plan to: Travel abroad for ≥3 mo Have intimate or sexual contact with local population Work in health care setting or may have contact with blood, blood products, or body fluids Count all doses; do not restart series even if time lapse between doses is greater than recommended interval. Accelerated schedule: 4 doses at 0, 7, 21–30 days and booster at 1 y
Human papillomavirus vaccine (HPV)	9 y For females and males 9–26 y Use HPV4 or HPV2 for females and HPV4 for males.	3 doses at 11–12 y at 0-, 2-, and 6-mo intervals	Recommended interval dose 1 to dose 2: 1–2 mo MI dose 1 to dose 2: 4 wk Recommended interval dose 1 to dose 3: 6 mo Recommended interval dose 2 to dose 3: 4 mo MI dose 2 to dose 3: 3 mo	
Influenza, trivalent or quadrivalent inactivated vaccine (TIV or QIV)	TIV and QIV: 6 mo; however, check product because minimum age varies by vaccine manufacturer.	Recommended annually for children ≥6 mo. Children aged 6 mo–8 y who are receiving influenza vaccine for first time: 2 doses Children >8 y and persons who previously received influenza vaccine: 1 dose	TIV and QIV: MI dose 1 to dose 2: 4 wk	Influenza can occur throughout the year in tropical countries. Peak influenza in temperate regions of the Southern Hemisphere occurs from April through September. In North America, influenza vaccine may not be available during the summer months. Travelers to the Southern Hemisphere should be vaccinated by the spring, if possible. Consider for travelers who are at high risk for complications from influenza for travel to tropics any time of year Southern Hemisphere from April through September Any destination where influenza outbreaks are occurring
Measles, mumps, rubella (MMR)	6 mo	2 doses at ages 12–15 mo and 4–6 y	Children 6–11 mo: 1 dose, then revaccinate at 12–15 mo and 4–6 y of age Children >12 mo vaccinated with 1 prior dose: 1 additional dose at least 4 wk after dose 1 Unvaccinated children >12 mo: 2 doses separated by 4 wk MI between doses: 4 wk	Do not administer MMR for 3 mo after immunoglobulin for hepatitis A prophylaxis; see <i>MMWR Morb Mortal Wkly Rep</i> 2005;54:Q1-4, for deferral times for blood products and immunoglobulin administered for other indications. Defer immunoglobulin administration for 2 wk after MMR vaccination. Monovalent vaccines are available for measles, mumps, and rubella. Combination MMRV (measles-mumps-rubella-varicella vaccine) can be used for children 12 mo–12 y but is associated with higher risk for fever and febrile seizures 5–12 days after the first dose among children 12–23 mo.

Meningococcal (quadrivalent A, C, Y, W135) Conjugate vaccine (MCV4) Polysaccharide vaccine (MPSV4)	MCV4-D (Menactra): 9 mo MCV4-CRM (Menveo): 2 mo MPSV4: 3 mo for serogroup A protection, standard recommended minimum age: 2 y (see indications)	MCV4-D or MCV4-CRM: routine vaccination, 1 dose for children at age 11–12 y and booster at 16 y. Administer 1 dose at 13–18 y of age if not previously vaccinated MCV4-D: 2 doses for travelers to risk areas ideally at 9 and 12 mo or at least 8 wk apart for children 9–23 mo MCV4-D or MCV4-CRM: 2 doses for travelers to risk areas at least 8 wk apart for children 24 mo–10 y MCV4-CRM: Can be given at 2, 4, and 12 mo	Meningococcal vaccination is required for travelers to annual Hajj in Mecca, Saudi Arabia. Vaccination is recommended for travel to sub-Saharan Africa during dry season (December through June) or for travel to any countries where epidemic is occurring. Recommended for all children with certain medical conditions. See <i>MMWR Morb Mort Wkly Rep</i> 2011;60:72-6.
Pneumococcal conjugate: 13-valent (PCV13)	6 wk	4 doses at ages 2, 4, 6, and 12–15 mo 1 dose for all healthy children 24–59 mo who are not completely vaccinated for age 1 supplemental dose of PCV13 for certain children who received 1 dose of PCV7: (1) all children 14–59 mo and (2) children 60–71 mo with underlying medical conditions	MIs between doses depend on age. Children receiving the first dose of vaccine at ≥ 7 mo require fewer doses to complete the series. Pneumococcal polysaccharide vaccine (PPV23) is routinely recommended for high-risk persons aged ≥ 2 years. See <i>MMWR Morb Mortal Wkly Rep</i> 2010;59(RR 11).
Polio: inactivated poliovirus vaccine (IPV)	6 wk	4 doses at ages 2, 4, 6–18 mo and 4–6 y Previously unvaccinated children: 3 doses MI between doses: 4 wk Preferred interval between dose 2 and dose 3: 2 mo Minimum age for dose 2: 10 wk Minimum age for dose 3: 14 wk Minimum age for dose 4: 18 wk Previously unvaccinated children < 4 y at completion of dose 3: 4 doses Previously unvaccinated children ≥ 4 y at completion of dose 3: 3 doses MI between doses: 4 wk If ≥ 4 doses are administered before 4 y, an additional dose should be given at 4–6 y. The final dose in the series should be administered on or after the fourth birthday and at least 6 mo after the previous dose.	Primary series is recommended for all travelers; booster dose for persons ≥ 18 y is recommended for travelers to some areas of Africa, Asia, and the Middle East; not routinely recommended for travel to Latin America. Single booster of IPV for previously vaccinated adults confers lifetime immunity. Oral poliovirus vaccine (OPV) is no longer recommended or available in the United States. For use in other countries, the World Health Organization recommends birth as the minimum age of administration. The MI between doses is 4 wk. OPV can be used for children younger than 6 wk traveling to areas with polio transmission.

TABLE 232.1 Routine Childhood Vaccinations and Accelerated Schedules and Modifications for Pediatric Travelers—cont'd

Vaccine	Minimum Age	Routine Schedule ^a	Accelerated Schedule and Modifications ^b	Indications for Use and Other Information ^c
Rotavirus (RV): RV1 (Rotarix) and RV5 (Rota Teq)	6 wk	RV1: 2 doses at ages 2, 4 mo RV5: 3 doses at 2, 4, and 6 mo	MI between doses: 4 wk; there is no maximum interval between doses Minimum age for dose 2: 10 wk Minimum age for dose 3: 14 wk	Maximum age for first dose in series is 14 wk, 6 days; and 8 mo, 0 days for final dose in series. Can be administered before, concurrently, or after administration of immunoglobulin. See CDC website for information about risk for intussusception with rotavirus vaccine.
Varicella	12 months	2 doses at 12–15 mo and 4–6 y	MI between dose 1 and dose 2 for children <13 y: 12 wk MI between dose 1 and dose 2 for persons ≥13 y: 4 wk Minimum age for dose 2: 15 mo	Do not administer varicella vaccine for 3 mo after immunoglobulin for hepatitis A prophylaxis; see <i>MMWR Morb Mortal Wkly Rep</i> 2005;54:Q1–4, for deferral times for blood products and immunoglobulin administered for other indications. Defer immunoglobulin administration for 2 wk after varicella vaccination. Combination MMRV can be used for children 12 mo–12 y but is associated with higher risk for fever and febrile seizures 5–12 days after the first dose among children 12–23 mo.

^aNumber of doses and recommended ages. Minimum age is the US recommendation unless otherwise noted. Recommendations in the US schedule may be different from those of the World Health Organization and other countries.

^bNumber of doses and MI between doses. *NOTE:* Interval represents time to dose.

^cContraindications: Anaphylactic reaction to prior dose or to any vaccine component or moderate-to-severe acute illness is a contraindication for all vaccines.

^dSee *MMWR Recomm Rep* 2006;55(RR-7):1–23.

^eCombination hepatitis A–hepatitis B (Twinrix) is available for use in persons ≥18 years. The vaccine, which is composed of inactivated viral components, is administered intramuscularly. The schedule involves 3 doses at 0, 1, and 6 months. It can be administered at an accelerated schedule of 4 doses at 0, 7, and 21–30 days and 1 year.

CDC, Centers for Disease Control and Prevention; *DTaP*, diphtheria and tetanus toxoids and acellular pertussis vaccine; *DT*, diphtheria-tetanus (toxoid); *IPV*, inactivated poliomyelitis vaccine; *MI*, minimal interval; *MMR*, mumps, measles, rubella; *PRP-OMP*, PRP-outer membrane protein conjugate vaccine; *Tdap*, tetanus, diphtheria, and pertussis; *Td*, tetanus and diphtheria (toxoid).

TABLE 232.2 Common Travel-Related Vaccines and Immunoglobulin for Children

Vaccine ^a	Vaccine Type	Route	Minimum Age	Primary Series ^b	Booster or Revaccination ^c	Accelerated Schedule	Protection After	General Indications for Use ^d
BCG	Live, attenuated bacteria	ID, SC	Birth	1 dose	None	None	2 mo after dose (WHO)	Consider for children <1 y who will be long-term travelers residing in high-risk areas to protect against meningococcal and miliary tuberculosis.
Immunoglobulin	Antibody from pooled human plasma	IM	Birth	1 dose	3–6 mo	None	Immediate	Use to prevent hepatitis A infection in children <1 y who are traveling to risk areas or for persons departing within 4 wk. Defer MMR and varicella vaccination for 3 mo after IG administered for hepatitis A prevention; defer the administration of IG for hepatitis A prevention for 2 wk after MMR or varicella vaccination. Defer rotavirus vaccine (RV) administration for 6 wk if possible. However, if 6-wk deferral would cause the first dose of RV to be scheduled for age ≥13 wk, a shorter deferral interval should be used to ensure that the first dose of RV is administered no later than age 13 wk.
Japanese encephalitis (IXIARO)	Inactivated virus	SC	2 mo	2 doses on days 0 and 28	Yearly for children age >17 y Booster: 1 dose	None	7 days after dose 2	Recommended for travelers who plan to spend a month or longer in endemic areas during the JEV transmission season. Consider for short-term travelers (<1 mo) to endemic areas during JEV transmission season if they plan to travel outside of urban areas and have an itinerary or activities that will increase their risk for JEV exposure; travelers to areas with an ongoing JEV outbreak; and travelers to endemic areas who are uncertain of specific destinations, activities, or duration of travel. Not recommended for short-term travelers whose visit will be restricted to urban areas or times outside of a well-defined JEV transmission season. See CDC website for further information. Clinicians should review updated data about risk areas because transmission varies by country and season. Destinations with transmission include to selected areas of Asia, Oceania (Australia and Papua New Guinea), Russia, especially long-term travelers to rural, agricultural endemic areas or epidemic regions during seasonal transmission (usually May to September).
Rabies	Human diploid cell vaccine (HDCV) Purified chick-embryo cell culture vaccine (PCEC)	IM	United States: None	3 doses at 0, 7, and 21 or 28 days	No boosters or serologic testing recommended for routine international travelers. Boosters and/or serologic testing recommended for high-risk groups. See CDC website for additional information.	None	14 days after dose 3	Mild adverse reactions (headache, myalgia, fatigue, influenza-like illness) reported in 13%–26% of vaccinees. There are no data on the use of IXIARO as a booster dose after a primary series with JE-VAX. Persons who received JE-VAX should receive the primary 2-dose series of IXIARO. Use for travelers to rabies-endemic countries. Vaccination is recommended for long-term travel in rural areas or in areas with limited access to health care. Travelers with extensive unprotected outdoor, evening, and nighttime exposure in rural areas, such as backpacking, should consider vaccination even for trips of short duration. Widespread worldwide rabies distribution. See Health Information for Travelers for list of countries that have not reported cases of rabies recently.

Continued

TABLE 232.2 Common Travel-Related Vaccines and Immunoglobulin for Children—cont'd

Vaccine ^a	Vaccine Type	Route	Minimum Age	Primary Series ^b	Booster or Revaccination ^c	Accelerated Schedule	Protection After	General Indications for Use ^d
Typhoid (ViCPS)	Capsular polysaccharide	IM	2 y	1 dose	2 y	None	14 days after dose	Postexposure vaccination is required even for persons who receive vaccination before exposure. After exposure in vaccinated person: 2 doses at 0, 3 days (no rabies immunoglobulin required). After exposure in unvaccinated person: Rabies immunoglobulin (RIG) (20 IU/kg) plus vaccination with 4 doses at 0, 3, 7, and 14 days. RIG can be administered up to and including day 7 of the postexposure prophylaxis series. Use recommended for travelers to Africa, Asia, and Latin America for long-term stays, travel outside usual tourist destinations, or travelers who desire maximal protection. Patients should be counseled about protective efficacy of vaccine (approximately 50–74% when studied in endemic areas) and importance of other preventive measures.
Typhoid oral (Ty21a)	Live, attenuated bacteria	Oral	6 y	4 doses at 0, 2, 4, 6 days	5 y	None	7–10 days after last dose	See indications for typhoid ViCPS. Patients should be counseled about protective efficacy of vaccine (approximately 60–85% when studied in endemic areas) and importance of other preventive measures. Must be swallowed (cannot be chewed) 1 h before meal, and vaccine must be refrigerated until administration. Do not administer within 72 h of any antibacterial agent, including doxycycline, Mefloquine, atovaquone-proguanil, and chloroquine can be administered concurrently. Contraindicated for immunocompromised patients.
Yellow fever	Live, attenuated virus	SC	6 mo	1 dose	10 y	None	10 days after dose	Use for travelers to selected areas of Africa and South America. Yellow fever has not been reported in Asia; however, some countries require proof of vaccination if the traveler is arriving from a yellow fever–endemic country. Yellow fever vaccination for children 6–9 mo should be discussed with an expert to weigh risk for adverse events against risk for yellow fever. Reports of rare serious adverse events of multiple organ system failure after vaccination. Contraindicated for patients who are immunocompromised or have allergy to eggs.

^aCholera vaccine is not available in the United States. Tick-borne encephalitis vaccine is not available in the United States. It is administered as a 4-dose series at 0, 28-day, 42-day, and 1-y intervals, with booster doses required every 3 to 5 y. The vaccine is available in Europe.

^bNumber of doses and recommended ages and intervals. *NOTE:* Interval represents time from dose.

^cNumber of doses and recommended ages and intervals.

^dContraindications: Anaphylactic reaction to prior dose or to any vaccine component or moderate-to-severe acute illness is a contraindication for all vaccines.

BCG, bacille Calmette-Guérin; CDC, Centers for Disease Control and Prevention; ID, intradermal; IG, immunoglobulin; IM, intramuscular; JEV, Japanese encephalitis virus; MMR, measles, mumps, rubella; SC, subcutaneous; WHO, World Health Organization.

and older, with a rate of one per 100,000 doses in people 60 to 69 years of age and 2.3 per 100,000 doses in people 70 years and older. The risk is thought to be approximately one per 200,000 to 300,000 doses in persons younger than 60 years and one per 40,000 to 50,000 doses in persons 60 years and older. The risk is greater in persons with a history of thymus disorder associated with abnormal immune cell function such as thymoma, myasthenia gravis, or DiGeorge syndrome.⁴⁷ Further studies are being conducted.^{63,126,167} In the interim, the CDC has recommended that, given the risk for serious illness and death from yellow fever,¹¹⁸ evidence of increasing transmission of the disease,¹⁴⁷ and the known effectiveness of the vaccine, clinicians should continue to use yellow fever vaccine.⁴³ Health care providers should carefully review travel itineraries to ensure that only people traveling to areas endemic for yellow fever or areas where yellow fever activity is reported receive yellow fever vaccine.^{25,27,43,180}

Japanese Encephalitis Virus

Japanese encephalitis is a viral infection transmitted by *Culex* mosquitoes that bite from dusk to dawn in an enzootic cycle between mosquitoes and vertebrate hosts, primarily pigs and wading birds. Japanese encephalitis virus (JEV) is primarily a disease of childhood, with most cases occurring among children younger than 15 years. Disease develops in less than 1% of infected persons.⁸¹ JEV occurs year-round in tropical regions and primarily from May through October in temperate zones. The risk is greatest for travelers to rural Asia, where the mosquito breeds in rice fields and other agricultural areas. Clinicians should consult the CDC Travelers' Health website for the current list of areas with endemic and epidemic transmission. JEV is associated with high rates of case fatalities and severe neurologic sequelae, especially in young children and older adults. Among an estimated 35,000 to 50,000 annual cases worldwide, approximately 20% to 30% of patients die, and 30% to 50% of survivors have neurologic or psychiatric sequelae.⁵⁸ However, JEV is rare among travelers, estimated at less than 1 per 1 million travelers. During 1973 to 2008, 55 cases of travel-associated JEV among persons from nonendemic countries were reported in the literature. Five (9%) of the cases occurred in children 10 years or younger.⁴³ Expatriates and travelers who stay for prolonged periods in rural areas likely have a risk similar to that of the local population in affected areas (5 to 50 per 100,000/year).⁴³ All travelers to risk areas should use personal protective measures, such as repellent and long-sleeved clothing, to minimize mosquito bites. Vaccination is recommended for travelers who plan to spend a month or longer in endemic areas during the JEV transmission season. Vaccination should be considered for travelers who will spend 30 days or longer in endemic areas during transmission season if they plan to travel outside of an urban area and have an itinerary or activities that will increase their risk for exposure; travelers to an area with an ongoing outbreak; and travelers to endemic areas who are uncertain of specific destinations, activities, or duration of travel. Consider vaccination for short-term travelers (<1 month) to endemic areas during transmission season if they plan to travel outside of urban areas and have an itinerary or activities that will increase their risk for exposure. Vaccination is not generally recommended for short-term travelers (<30 days) whose visit will be restricted to urban areas or times outside of a well-defined transmission season.⁴³ IXIARO, an inactivated JEV vaccine, has been licensed for use in children 2 months and older in the United States since 2013.⁴⁹ IXIARO is administered as a two-dose series, with the second dose administered 28 days after the first dose. In children older than 17 years, if the primary series of IXIARO was administered 1 year or more previously, a booster dose should be given before potential reexposure or if there is a continued risk for JEV infection. The safety of a booster dose in children younger than 17 years has not been established. JE-Vax, an inactivated mouse brain-derived vaccine, was licensed in the United States in 1992 for use in travelers 1 year and older. In 2006, JE-Vax production was discontinued, and all remaining doses expired in May 2011. Other inactivated and live, attenuated JEV vaccines are manufactured and used in Asia but are not licensed for use in the United States.

Rabies

Rabies virus, which causes a progressive fatal encephalomyelitis, occurs worldwide, except in Antarctica. In certain areas of the world, including

(but not limited to) parts of Africa, Asia, and Central and South America, canine rabies remains highly endemic. Rabies also occurs in other wild animals, including bats. The three-dose preexposure rabies vaccine should be considered for children visiting rabies-endemic countries for longer than 1 month, those undertaking extensive outdoor activities such as backpacking or camping in endemic countries, or children traveling to areas where access to health care is limited. Persons who completed the three-dose preexposure vaccine series or the full post-exposure prophylaxis and are considered preimmunized do not require routine boosters. Routine booster doses and/or serologic testing are recommended for certain high-risk persons working with rabies virus or for persons, such as cavers, with frequent exposure to mammals, such as bats. To reduce the risk for acquiring rabies, children and their families should be counseled to stay away from stray dogs and other animals, especially if traveling to Latin America, Asia, or Africa.⁴³ Exposure is considered a medical emergency. Wound management should include thorough cleansing with soap, water, and povidone-iodine, if available, and suturing delay of a few days, if possible. Postexposure prophylaxis should be administered as soon as possible; travelers who received preexposure vaccination should receive two booster doses on days 0 and 3 after exposure, whereas persons who did not receive preexposure vaccination should receive rabies immunoglobulin and a series of four injections of rabies vaccine over 14 days.^{125,149}

Typhoid

Typhoid infection is an acute, life-threatening illness caused by *Salmonella enterica* serotype Typhi, which is usually acquired through contaminated food and water. Serotypes Paratyphi A, Paratyphi B, and Paratyphi C can also cause a protracted bacteremic illness referred to as paratyphoid fever. Enteric fever can be severe and even life-threatening, with a case-fatality rate of more than 10% if not recognized and treated appropriately.¹⁵⁶ The incubation period is 6 to 30 days, and illness onset is insidious with gradually increasing fatigue, fever, malaise, headache, and anorexia. A transient malar rash can occur.

Approximately 90% of US cases occur among persons returning from foreign travel, with more than 75% with travel to India, Bangladesh, or Pakistan.⁵⁵ Vaccination is recommended for pediatric travelers visiting developing countries, especially for prolonged periods, or traveling outside the usual tourist destinations. Travelers visiting friends and relatives are at increased risk. Two vaccines are available in the United States: (1) an attenuated, live oral vaccine that can be administered to children 6 years of age and older and (2) an injectable Vi capsular polysaccharide vaccine that can be administered to children starting at 2 years of age and that requires a booster every 2 years. The oral vaccine consists of four capsules, one taken every other day, and should be completed 1 week before travel. Boosters should be administered every 5 years. Because the oral typhoid vaccine is a live, attenuated vaccine, it should not be administered to individuals with immunodeficiency, acute febrile illness, or gastrointestinal disease.^{12,103} Furthermore, the oral typhoid vaccine should not be administered within 72 hours of antibiotics. However, antimalarials, including atovaquone/proguanil, can be given concurrently with oral typhoid vaccine because this medication did not appear to diminish antibody titers after vaccination in a double-blind, placebo-controlled study involving 330 Gabonese school children.⁷⁷ There are no efficacy studies among travelers from nonendemic areas, but both vaccines have moderate efficacy in populations where typhoid disease is endemic, with efficacy rates ranging from 30% to 80% depending on the location and the age range studied.^{12,157} Therefore parents should be cautioned that vaccination is not 100% effective, and precautions regarding safe food and water should be followed.⁴³

Cholera

Cholera is a diarrhea illness caused by *Vibrio cholerae*, a gram-negative bacteria that can cause watery diarrhea leading to severe dehydration. Cholera primarily affects individuals in resource-limited settings with inadequate access to clean water and is mostly endemic in parts of Africa and Asia. However, massive epidemics do occur with the introduction of *V. cholera* into a naïve population. Most recently, there was a large outbreak in Haiti beginning in October 2010 with the introduction

of *V. cholera* O1 variant El Tor strain, possibly through the United Nations stabilization forces after a large earthquake. Within 3 years, there were 692,098 cholera cases, of which 386,652 patients were hospitalized and 8470 died, giving a case-fatality rate of 1.2%.^{64,140} Cholera is easily treatable with oral rehydration salts. In severely dehydrated patients, antibiotics diminish the duration of diarrhea and reduce the volume of rehydration fluids required. In June 2016, Vaxchora, a live, attenuated oral vaccine, was approved by the FDA for prevention of cholera caused by serogroup O1 in adults 18 to 64 years old traveling to affected areas, showing an efficacy of 90% 10 days after administration of one dose. Efficacy waned to 80% 3 months after vaccination.¹⁶³ Outside the United States, two different killed whole-cell oral vaccines exist with studied efficacy in children. Dukoral can be administered to adults and children aged 6 years or older in two doses. It can be given to children older than 2 years but younger than 6 years in three doses, and it provides protection 1 week after the last dose. Field trials in Bangladesh and Peru have shown that this vaccine is safe and effective, conferring protection with 85% efficacy for 4 to 6 months. Shanchol is given as two doses 2 weeks apart in children older than 1 year and provides 67% protection against clinically significant O1 cholera for 2 years.^{86,179} As of 2013, an oral cholera stockpile was established for outbreak control and emergencies, and this has been used in a reactive campaign during cholera outbreaks as well as in preemptive vaccination campaigns in patients at high risk for cholera due to humanitarian crises.

PREVENTION OF MOSQUITO-BORNE ILLNESS

During a travel assessment, recommendations to prevent vector-borne diseases, including malaria, yellow fever virus, JEV, chikungunya virus, and dengue virus, should be determined by a comprehensive review of the travel itinerary and planned activities. The risk for acquiring an infectious disease differs and is probably greater for an adolescent who is participating in a rural home-stay program for 3 months than for a 5-year-old child traveling with parents to a beach resort. Furthermore, expatriates who live abroad and foreign-born persons, especially immigrants, refugees, and their children visiting friends and relatives in their home country, have health risks different from those of short-term travelers who are visiting tourist destinations.

Malaria

Malaria is a parasitic infection caused by one of four species of *Plasmodium*: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, or *Plasmodium malariae*. It is transmitted by the bite of an infective female *Anopheles* mosquito. Malaria is endemic in more than 100 countries on five continents; transmission occurs primarily in the tropic and subtropical regions of sub-Saharan Africa, Asia, Latin America, the Caribbean, the Middle East, and Oceania. Globally, malaria is responsible for 250 million clinical infections and nearly 1 million deaths annually, with most caused by *P. falciparum*, principally in young children and pregnant women.^{184,176}

An estimated 10,000 to 30,000 travelers from industrialized countries are thought to contract malaria each year, but these numbers probably are underestimated because they do not include travelers in whom malaria was diagnosed and treated abroad.^{105,106,120,175} The number of malaria cases reported in 2010 in the United States was the largest since 1980. In 2010, 1691 cases of malaria, including nine fatal cases, were reported to the CDC. All fatal cases were *P. falciparum*, and seven were acquired in West Africa. Among the 898 cases in US civilians for whom information on chemoprophylaxis use and travel area was known, only 45 (5%) reported that they had followed and adhered to a chemoprophylactic drug regimen recommended by the CDC for the areas to which they had traveled. Among the 1573 cases among patients for whom age was known, 232 (15%) occurred in persons younger than 18 years. Among the 232 cases among persons younger than 18 years, 108 (47%) occurred among US civilian children, 101 (44%) occurred among children of persons categorized as having a foreign resident status at the time their malaria infection was acquired, and 23 (10%) occurred among children of unknown resident status. Of the 108 cases among US civilian children, four (4%) were younger than 24 months, 10 (9%) were 2 to 4 years, 54 (50%) were 5 to 12 years, and 40 (37%)

were 13 to 17 years of age. Of these cases among US civilian children for whom country of exposure was known, 75 (75%) were attributable to travel to Africa. Among the 83 US civilian children for whom reason for travel was known, 69 (83%) were visiting friends and relatives, 10 (12%) were traveling for educational purposes, two (2%) were traveling for missionary work, and two were either tourists or specified as other. Of the 85 children for whom chemoprophylaxis information was known, 26 (31%) were reported as having taken prophylaxis, of whom 16 (62%) had taken an appropriate regimen; however, only five (31%) of these patients reported adherence.³²

Reviews of deaths attributed to malaria in the United States indicate that failure to take or to adhere to recommended antimalarial chemoprophylaxis, promptly seek medical care for posttravel illness, and promptly diagnose and treat suspected malaria contributed to fatal outcomes.^{28,123,137} Retrospective reviews of malaria in children also have found that a substantial proportion of cases occurred in recent immigrants and the children of former immigrants who had traveled to visit their family's country of origin.^{18,96,146} These data highlight the importance of pretravel assessment and counseling, particularly for foreign-born persons, who may assume they are protected by natural immunity or do not perceive the risk for acquisition of malaria by their children who accompany them on returning to visit their home country. The CDC recommends that prevention messages directed toward Africa-bound travelers, particularly those whose destination is West Africa, should be emphasized in early spring, accompanied with a reminder in late fall through early winter. Malaria prevention messages directed toward Asia-bound travelers, specifically those bound for India, should be intensified in late spring.¹²³

Dengue

A variety of pathogens increasingly are being recognized as emerging infectious diseases in travelers. In addition to malaria, other vector-borne infectious diseases are among the important diseases for consideration in travelers. Dengue is one of the most significant vector-borne viral infections worldwide. It is endemic in at least 100 countries in Asia, the Pacific, Africa, Latin America, and the Caribbean and occurs sporadically in the Middle East. Worldwide, an estimated 50 to 100 million cases of dengue fever occur annually, including 500,000 dengue hemorrhagic fever cases and 22,000 deaths, mostly among children.⁵³ Dengue fever has been reported among 2% to 14% of ill travelers.^{16,85,138,171}

Epidemics of dengue hemorrhagic fever, the more severe clinical form of dengue fever, occur every 3 to 5 years in Southeast Asia and are an emerging problem in Latin America.¹³⁹ Epidemics caused by all four serotypes (1–4) have become progressively more frequent and larger in the past 25 years. In addition, most tropical urban centers in endemic regions have multiple dengue virus serotypes cocirculating (hyperendemicity), which increases the risk for dengue transmission and the risk for dengue hemorrhagic fever.⁴² Outbreaks of dengue fever also have occurred in Hawaii, Puerto Rico, the US Virgin Islands, Samoa, and Guam and along the United States–Mexico border.^{53,57,58,143} In a recent short report by Krishnan and associates,¹¹² eight children were diagnosed with dengue between 2007 and 2010 at Bronx-Lebanon Hospital Center in New York City. The cases had a median age of 13.6 years (range, 0.3–17.6 years). All of the children were visiting friends and relatives in Puerto Rico (12%) or the Dominican Republic (88%). Of the eight children, three (38%) developed complications, including dengue shock syndrome in one infant.¹¹² Dengue is transmitted primarily by day-biting *Aedes aegypti* mosquitoes, which breed in flower vases, barrels, and discarded tires that collect water. Transmission occurs in rural and urban areas, but the risk is greatest in urban areas. Prevention should focus on protection against mosquito bites. Travelers to areas of risk should be counseled to apply repellent during the day, even while visiting cities. No vaccine is available, and previous infection with one of the four serotypes does not protect against infection with another serotype. The risk for contracting dengue hemorrhagic fever increases after subsequent infection with a different serotype.¹⁵⁹

Chikungunya

Chikungunya virus is an alphavirus that exists in tropical Africa and is transmitted by the bite of an infected mosquito. Because chikungunya

fever epidemics are sustained by human-mosquito-human transmission, the epidemic cycle is similar to the cycles of dengue and urban yellow fever. Infection is associated with fever, headache, severe joint pain, and, in approximately half of the cases, a generalized maculopapular rash similar to that of dengue virus infection. Complications are more common in children younger than 1 year. Large outbreaks of chikungunya have been reported recently on several islands in the Indian Ocean and in India, and the disease has now been locally transmitted in 45 countries. The first cases of locally transmitted disease in the United States occurred in Florida in 2014, and this disease has been widely reported in Puerto Rico.^{109,154} Almost 1.8 million cases have been reported as of 2016.⁵⁰ No vaccines or specific preventive medications are available; therefore, prevention measures should focus on personal protection against mosquito bites and awareness of local epidemics.³⁶

Zika Virus

Zika virus is an arthropod-borne flavivirus transmitted by the *Aedes* mosquito. It can also be transmitted sexually, through blood transfusions, or through vertical transmission from mother to child. Outbreaks have occurred in the past in Africa, Southeast Asia, and the Pacific Islands. Beginning in 2014, Zika virus was detected in Chile, and it continues to contribute to an epidemic that involves 41 countries and territories in the Americas and Caribbean.¹³ More than 80% of infected individuals do not have symptoms. In the 20% who do have symptoms, they are often nonspecific and include low-grade fevers, pruritic rash, nonpurulent conjunctivitis, and arthralgia of the hands and feet. The two complications of Zika virus infection include Guillain-Barré syndrome and neurologic complications in infants born to infected mothers, including congenital microcephaly.¹⁹ Although Zika virus has been detected in Puerto Rico and the Virgin Islands, all the cases in the continental United States have been imported.⁵² There is no specific treatment recommended for infection, and prevention of disease largely depends on mosquito avoidance through personal protective measures. Pregnant women and their partners are discouraged from traveling to locations where there is local transmission of Zika virus, and men are encouraged to abstain from sex or to use condoms during a woman's pregnancy because the virus can persist in semen for weeks if not months.¹⁴

Personal Protection Methods

Prevention of mosquito-borne illnesses in pediatric travelers depends first on obtaining current and accurate information about the risk for acquiring these diseases in proposed travel destinations and determining whether planned activities, such as rural versus urban travel and the season of travel, place the traveler at increased risk for exposure. Information on the geographic- and country-specific risks for acquiring infections is available from multiple sources. Selected websites with information about the country-specific risk for acquiring diseases are listed in this chapter in the discussion on international travel information resources.

The first mainstay of prevention of mosquito-borne illnesses is appropriate and effective use of personal protection measures. All travelers to malaria-endemic areas should be counseled on recommended measures to avoid bites from *Anopheles* mosquitoes, which typically are evening and nighttime feeders, versus the *Aedes* mosquitos, which are daytime feeders. Such measures include wearing clothing that reduces the amount of exposed skin (e.g., long-sleeved shirts, long pants tucked into socks, hats, stroller nets) and, whenever possible, remaining in well-screened or enclosed air-conditioned areas. Travelers staying overnight in facilities without air conditioning or screens should use insecticide-treated mosquito nets over the beds. Stroller nets can be used for children in strollers. Bed nets that have been treated with insecticide such as permethrin are more effective in preventing malaria than are untreated bed nets and are safe for children.¹³⁶ Travelers can purchase permethrin to spray on the bed nets or purchase pretreated (or impregnated) bed nets. Permethrin also can be sprayed on clothing, but it should not be applied directly to skin. Permethrin remains effective through multiple washings. Clothing and bed nets should be retreated according to the product label. Permethrin should not be applied to the skin. Although permethrin provides longer duration protection, recommended repellents that can be applied to skin (DEET [*N,N*-diethyl-*m*-toluamide], picaridin, oil of lemon eucalyptus [OLE], or *para*-menthane-3,8-diol [PMD], the

synthesized version of OLE]), and IR3535 can also be used on clothing and mosquito nets. During the evening, insecticide also can be sprayed inside rooms.

Another important focus of counseling for personal protection measures is appropriate use of insect repellent on exposed skin. The CDC recommends the use of repellent products with active ingredients registered with the US Environmental Protection Agency (EPA). Products containing the following active ingredients provide long-lasting protection (DEET, picaridin (KBR 3023), IR3535, and OLE or PMD, the synthesized version of OLE. Note that "pure" oil of lemon eucalyptus (essential oil) is not the same product as OLE insect repellent. Some controversy has occurred regarding the recommended concentration of DEET for pediatric use. In 1998, the EPA conducted an extensive review of DEET safety. The agency concluded that no evidence indicates that DEET is toxic to infants or children. Additional evaluations have not demonstrated a link between seizures and topical use.^{43,54}

Most repellents can be used on children older than 2 months, with the following considerations: (1) products containing OLE specify that they should not be used on children younger than 3 years; (2) repellent products must state any age restriction (if none is stated, the EPA has not required a restriction on the use of the product); and (3) many repellents contain DEET as the active ingredient. DEET formulations of up to 50% can be used for children older than 2 months. The concentration of DEET affects the duration of protection. Higher concentrations provide longer protection; however, the duration of protection reaches a plateau at approximately 30% to 50%. Therefore most clinicians recommend products having up to 30% for children. The American Academy of Pediatrics recommends that 30% or lower DEET should be used on children older than 2 months and that repellents with DEET should not be used on infants younger than 2 months (<https://www.epa.gov/insect-repellents>).³ In a laboratory study, a product with 23.8% DEET provided an average of 5 hours of protection (range, 3–6 hours) and a product with 6.65% DEET provided an average of 2 hours of protection (range, 1.5–2.8 hours). Duration of protection may be affected by the environmental temperature, sweating, and wind conditions.^{25,54,83,87} Products that contain repellents and sunscreen generally are not recommended because of the need to reapply sunscreen more frequently than repellent.^{6,8,134} Mosquito coils should be used with extreme caution in the presence of children to avoid burns and inadvertent ingestion.⁶⁰

Clinicians are encouraged to stress to parents and children alike the importance of using personal protection measures. Despite the demonstrated efficacy of these measures, studies have found that only 17% of adult travelers with malaria reported using insect protection methods and only 11% took the recommended chemoprophylaxis.¹⁰⁵

Antimalarial Medication

Other than personal protective measures, patients traveling to malaria-endemic regions should be encouraged to further protect themselves by using chemoprophylaxis. Selection of the appropriate drug for antimalarial chemoprophylaxis must be based on numerous factors: the most recent information available about malaria in the proposed travel destinations; the trip itinerary; the age, weight, and medical history of the traveler; the personal preference for the frequency of dosing and the duration of chemoprophylaxis on return from the trip; and the cost of medication. These decisions can be challenging for primary care providers and clinicians with limited experience in infectious disease and travel medicine, so when in doubt, clinicians should seek the advice of a travel medicine or infectious disease expert. In addition, the CDC provides resources with guidance on appropriate use of and recommended regimens for antimalarial chemoprophylaxis (listed in the section on international travel information resources).

Fig. 232.1 outlines an algorithm for determining appropriate antimalarial chemoprophylaxis regimens for pediatric travelers. Because data on the distribution of drug-resistant malaria are evolving constantly, clinicians always should obtain the most recent information about the risk for malaria and zones of drug resistance from the CDC website or other sources of information before prescribing malaria chemoprophylaxis.^{38,43,153}

The first decision point in selecting appropriate antimalarial chemoprophylaxis is whether travel is occurring in a region of chloroquine-sensitive or chloroquine-resistant malaria. For travel to areas with

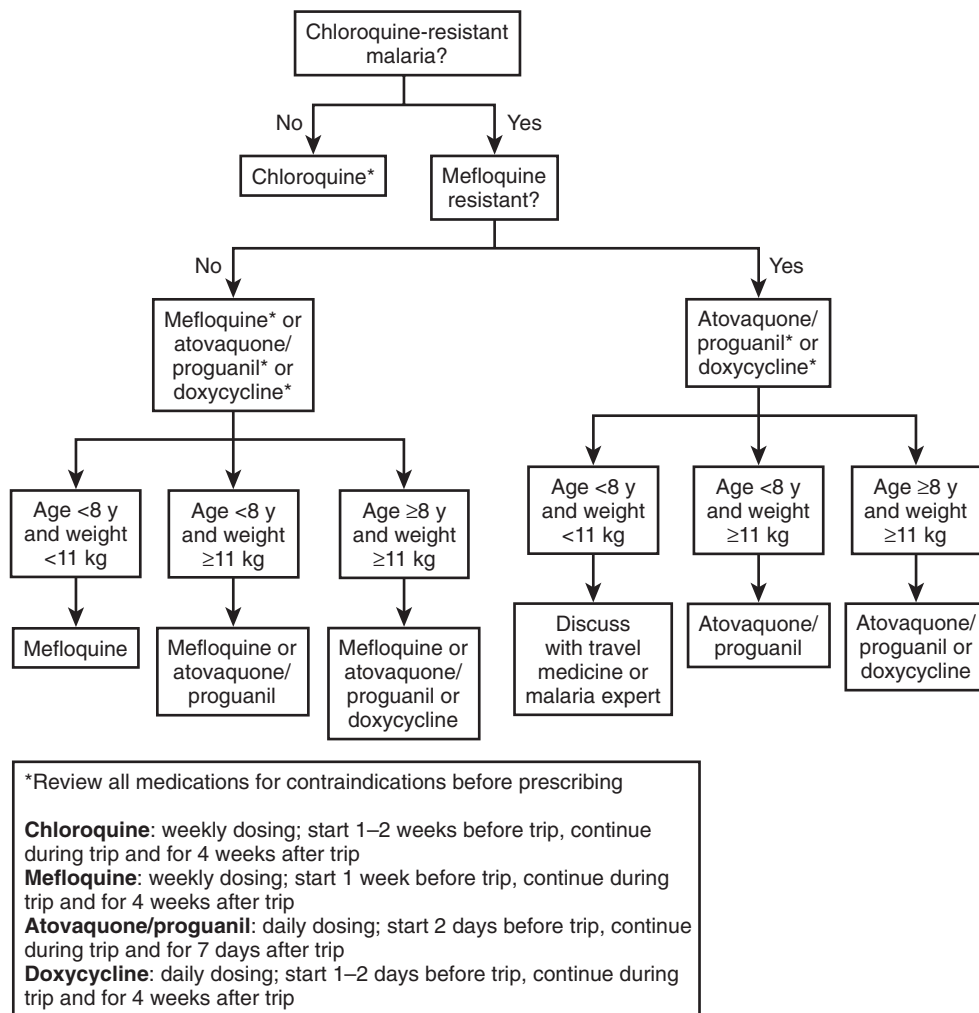

FIG. 232.1 Algorithm for determining appropriate antimalarial chemoprophylaxis regimens for pediatric travelers.

chloroquine-sensitive malaria, chloroquine is the drug of choice for antimalarial chemoprophylaxis. *P. ovale*, *P. malariae*, and most *P. vivax* are widely sensitive to chloroquine; however, chloroquine-resistant *P. vivax* is an emerging problem and has been reported from Guyana, Papua New Guinea, India, Burma (Myanmar), and areas of Indonesia.^{42,105} In addition to chloroquine-resistant *P. vivax*, chloroquine-resistant *P. falciparum* has been reported from these areas, and consequently chloroquine would not be recommended as chemoprophylaxis for travelers to these regions. Chloroquine-sensitive *P. falciparum* exists in parts of the Caribbean, Central America, the Middle East, and China.^{43,107}

If the traveler is visiting a region with chloroquine-resistant malaria, the next decision point is whether travel will include regions with chloroquine-resistant malaria only or both chloroquine- and mefloquine-resistant malaria. In some regions, *P. falciparum* may be resistant to both chloroquine and mefloquine; these areas currently are limited to the borders of Thailand with Myanmar (Burma) and Cambodia, the western provinces of Cambodia that border Thailand, and the eastern states of Myanmar (Burma) on the border between Burma and China, along the borders of Laos and Burma, the adjacent parts of the Thailand-Cambodia border, and southern Vietnam.^{43,107} For travel to areas with chloroquine-resistant malaria, three current antimalarial chemoprophylaxis options are mefloquine (Lariam), atovaquone/proguanil (Malarone), and doxycycline. The CDC no longer recommends the use of chloroquine-proguanil for chemoprophylaxis in chloroquine-resistant areas. For travel to areas with chloroquine-resistant and mefloquine-resistant malaria, either atovaquone-proguanil or doxycycline can be used. Primaquine can be used as an option for primary prophylaxis in

special circumstances. Clinicians should contact the CDC Malaria Hotline (770-488-7788 or 1-855-856-4713) for additional information. Primaquine also can be used for terminal prophylaxis to prevent relapses of *P. vivax* or *P. ovale*. In general, terminal prophylaxis is indicated only for persons who have had prolonged exposure to malaria-endemic areas (e.g., missionaries and expatriates).⁴³

In evaluating options for antimalarial chemoprophylaxis, physicians should review each medication for contraindications and weight and age restrictions (Table 232.3). Pediatric doses of medications used for treatment should be calculated on the basis of body weight. Medications used for infants and young children are the same as those recommended for adults, except under the following circumstances: doxycycline should not be given to children younger than 8 years because of the risk for teeth staining, and atovaquone-proguanil should not be used for prophylaxis in children weighing less than 5 kg because of lack of data on safety and efficacy.

Chloroquine is relatively well tolerated in children. In the United States, chloroquine is available in tablet form; in Europe and other countries, it is also available as a syrup. Mefloquine can be used safely in children weighing less than 9 kg and may be useful for longer trips because it is administered once weekly.¹²¹ However, it must be continued for 4 weeks after leaving the malarious area, and no liquid preparation is available. Doses for children are one-fourth, one-half, and three-fourths of a tablet, depending on weight. Mefloquine has been associated with rare but serious adverse reactions (e.g., psychoses and seizures) at prophylactic doses; these reactions are more frequent with higher doses used for treatment. Other side effects that have occurred

TABLE 232.3 Antimalarial Chemoprophylaxis Regimens for Pediatric Travelers

Medication	Regimen	Dose	Contraindications and Precautions	Side Effects	General Indications and Information for Use
Chloroquine (Aralen)	Weekly starting 1–2 wk before trip Continue weekly during trip and for 4 wk after trip	5 mg base/kg (8.3 mg salt/kg) up to 300 mg base (500 mg salt) Tablets: 300 mg base (500 mg salt)	Prior retinal or visual field changes Psoriasis (may be exacerbated by chloroquine)	Gastrointestinal symptoms, seizures, rash, headache, dizziness, pruritus (especially in dark-skinned persons), blurred vision, decreased hearing, tinnitus, retinal damage at high cumulative doses ^a High toxicity in overdoses, keep out of reach of children	Use only in areas of chloroquine-sensitive malaria. Limited usefulness because of widespread chloroquine resistance. Bitter taste.
Mefloquine (Lariam)	Weekly starting 1 wk before trip Continue weekly during trip and for 4 wk after trip	≤9 kg: 5 mg/kg/dose once weekly 9–19 kg: 62.5 mg ($\frac{1}{4}$ of 250 mg tablet) once weekly 20–30 kg: 125 mg ($\frac{1}{2}$ of 250 mg tablet) once weekly 31–45 kg: 187.5 mg ($\frac{3}{4}$ of 250 mg tablet) once weekly ≥45 kg: 250 mg once weekly Tablets: 228 mg base (250 mg salt)	Psychiatric conditions, cardiac conduction disorders, seizure disorders, persons with known hypersensitivity to mefloquine Should not take with quinine-like drugs	Gastrointestinal symptoms, dizziness, insomnia Occasional serious adverse effects: seizures, nightmares, depression, anxiety, psychosis, especially in persons with these preexisting medical conditions	Use in areas with chloroquine-resistant malaria. Advantageous for long-term travelers because of weekly dosing and less costly than atovaquone-proguanil. Bitter taste.
Atovaquone-proguanil (Malarone)	Daily starting 1–2 days before trip Continue daily during trip and for 7 days after trip	5–8 kg: $\frac{1}{2}$ pediatric tablet once daily 8–10 kg: $\frac{3}{4}$ pediatric tablet once daily 10–20 kg: pediatric tablet once daily 20–30 kg: 2 pediatric tablets once daily 30–40 kg: 3 pediatric tablets once daily ≥40 kg: 1 adult tablet daily Pediatric tablets: 62.5 mg atovaquone and 25 mg proguanil hydrochloride Adult tablets: 250 mg atovaquone and 100 mg proguanil hydrochloride	Contraindicated in severe renal failure Not recommended or use with caution for children <11 kg, pregnant or lactating women Do not take with tetracycline, metoclopramide, rifampin, or rifabutin (all reduce concentrations of atovaquone)	Gastrointestinal symptoms, headache, loss of appetite, dizziness, pruritus	Use in areas with chloroquine-resistant or mefloquine-resistant malaria. Advantageous for short-term travelers because prophylaxis can be stopped 1 week after leaving malaria area. Available in pediatric tablets. Take with food or milk.
Doxycycline	Daily starting 1–2 days before trip Continue daily during trip and for 4 wk after trip	2 mg/kg up to 100 mg daily Tablets: 50 mg, 100 mg	Do not use for children <8 y, pregnant or lactating women Do not give within 3 h of antacids, iron or Pepto-Bismol Do not administer oral typhoid vaccine within 72 h of doxycycline	Gastrointestinal symptoms, photosensitivity, increased blood urea nitrogen level, hypersensitivity reactions, blood dyscrasias, vaginal candidiasis May decrease the effectiveness of oral contraceptives	Use in areas with chloroquine-resistant and mefloquine-resistant malaria (borders of Thailand with Myanmar [Burma] and Cambodia, the western provinces of Cambodia that border Thailand, and the eastern states of Myanmar [Burma], on the border between Burma and China, along the borders of Laos and Burma, the adjacent parts of the Thailand-Cambodia border, and in southern Vietnam. Take with food; taking with food or milk can decrease gastric irritation (absorption of doxycycline is not significantly decreased by simultaneous administration of milk or food).

^aDespite the use of chloroquine as an antimalarial chemoprophylaxis agent for decades and the use of high-dose chloroquine for certain chronic diseases, the literature is inconclusive about the potential risk for retinopathy associated with long-term use of chloroquine for antimalarial prophylaxis. Retinopathy has rarely been reported in patients receiving weekly prophylaxis. Retinopathy appears to be related to dosage and accumulated dosage.

in chemoprophylaxis studies include depression, anxiety disorder, mood changes, panic attacks, and other neuropsychiatric symptoms. Mefloquine is contraindicated in travelers with active depression, a recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. It carries a US Boxed Warning that it may cause neuropsychiatric adverse effects that can persist after mefloquine has been discontinued. During prophylactic use, if symptoms occur, an alternative medication should be used. It should be used with caution in people with a history of depression or psychiatric disorders. For children who weigh 5 kg or more and are at risk for acquiring chloroquine-resistant *P. falciparum* infection, atovaquone-proguanil can be advantageous for short trips because it is started 1 to 2 days before the trip commences and can be stopped 7 days after the trip. However, the patient or parent must remember to take or to administer the medication daily. It is available in pediatric tablet form. Doxycycline is contraindicated in children younger than 8 years because of concern about the propensity of tetracyclines to stain growing teeth or potentially affect developing bones. For older children, doxycycline must be administered daily and continued for 4 weeks after departing the malaria-endemic area.^{43,107}

Chloroquine, mefloquine, and atovaquone-proguanil have a bitter taste. Before departure, pharmacists can be asked to pulverize tablets and prepare gelatin capsules with calculated pediatric doses. Mixing the powder in a small amount of food or drink can facilitate the administration of antimalarial drugs to infants and children. Additionally, any compounding pharmacy can alter the flavoring of malaria medication tablets so that they are more willingly ingested by children. Assistance with finding a compounding pharmacy is available on the International Academy of Compounding Pharmacists' website (<http://www.iacprx.org>). Because overdose of antimalarial drugs, particularly chloroquine, can be fatal, medication should be stored in childproof containers and kept out of the reach of infants and children.

The importance of determining appropriate antimalarial chemoprophylaxis regimens for travelers and counseling to improve compliance cannot be overemphasized. In retrospective reviews of pediatric malaria cases, between 75% and 100% of infected children had received inadequate or no chemoprophylaxis.^{43,146,169} Finally, effective pretravel malaria prevention counseling includes anticipatory guidance for parents about recognition of and response to symptoms of malaria infection in young pediatric travelers. Parents should be counseled that although compliance with personal protection measures and chemoprophylaxis will decrease the risk, it cannot guarantee prevention of malaria infection. They should be instructed about the symptoms of malaria infection, such as fever, headache, vomiting, diarrhea, and myalgia, and be counseled to seek immediate medical attention if symptoms occur. Delay in recognition and treatment of malaria is associated directly with an increase in rates of morbidity and mortality; therefore prompt and appropriate initiation of effective therapy is paramount.^{43,91,106,158,175} Parents also should be advised that some types of malaria can become symptomatic several weeks to months after exposure, and therefore prompt medical attention should be sought even if illness develops in a child months after international travel to malaria-endemic areas.

PREVENTION OF TRAVELER'S DIARRHEA IN CHILDREN

Epidemiology of Traveler's Diarrhea

One of the most difficult tasks faced by international travelers of any age is ensuring the safety of food and water. Traveler's diarrhea refers to diarrhea that develops during travel or within 14 days of travel, and is most often caused by the ingestion of contaminated food and water. It is typically defined as the occurrence of three or more unformed stools within a 24-hour period with at least one of the following signs or symptoms: temperature higher than 38°C (100.4°F), abdominal cramping, nausea, vomiting, fecal urgency, tenesmus, or blood or mucus in stools.^{74,76,82,141} Traveler's diarrhea affects approximately 20% to 50% of adult travelers and 10% to 41% of children and is the health problem most frequently reported by travelers to developing countries.^{73,74,82} It can occur any time during travel but typically occurs within the first week or two of the trip. The illness usually is self-limited, and for adults

the average duration of illness has been reported to be 3 to 5 days.⁷⁶ Analysis from the GeoSentinel Surveillance Network shows that among 1840 children returning from 218 global destinations, diarrhea was the most common complaint with 28% of children listing it as their travel-related health issue, with bacteria causing 29% of the cases.⁹⁰ During 2004 to 2009, 24% of all travel-related enteric infections in the United States occurred in children. The main causative agents included *Campylobacter* (42%), nontyphoidal *Salmonella* (32%), and *Shigella* (13%). Of 328 children who sought care for travel-associated illness at the emergency department of the University of Zürich Children's Hospital, 129 (39%) had a diarrheal illness, including three with *Salmonella typhi* and two with *Salmonella paratyphi* infection. The proportion of children with diarrhea increased with age—33% in children age 0 to younger than 2 years, 39% in children 2 to 5 years and younger, and 45% in children 6 to 16 years of age. Among the ill pediatric travelers visiting family and relatives, 41% had diarrhea.⁹⁸ In a study of 890 children younger than 20 years presenting to the outpatient travel clinic of the University of Munich after travel to the tropics and subtropics and their associates, 25% had acute diarrhea, the most frequent syndrome among all ill travelers. The most frequently diagnosed infectious enteric pathogens were giardiasis (8%), *Campylobacter* enteritis (4%), *Salmonella* enteritis (4%), and amebiasis (3%).⁹⁵ A retrospective study of Swiss children who had visited the tropics or subtropics reported finding similar incidence rates of traveler's diarrhea in children—40%, 8.5%, 21.7%, and 36% in children aged 0 to 2, 3 to 6, 7 to 14, and 15 years and older, respectively. In this study, the authors also found that young children (0–2 years old) most frequently were affected with traveler's diarrhea and that the clinical course tended to be more severe and prolonged than in older children. Overall, children were found to have longer lasting illness than that noted in adults, with an average duration of 11 days for all children combined and 29 days for small children.¹⁴²

Enteric pathogens typically are isolated from approximately 50% to 75% of stool specimens from adult travelers with diarrhea; in the remainder, usually no pathogen is isolated. Pathogen varies by location of travel, but in general, *Escherichia coli*, especially enterotoxigenic *E. coli*, is the most common overall cause of traveler's diarrhea, especially in Latin America and Africa, followed by *Campylobacter*, *Salmonella*, and *Shigella*. Other, less common causes of etiologic agents include pathogenic bacteria, such as *Aeromonas* and *Plesiomonas*; protozoa (e.g., *Giardia lamblia*, *Entamoeba histolytica*, *Cryptosporidium* spp., and *Cyclospora cayentanensis*); viruses, such as rotavirus and Norwalk-like viruses; and, rarely, helminths.¹⁴¹ Numerous risk factors for traveler's diarrhea, including the consumption of certain high-risk foods (i.e., raw foods such as meats, seafood, and vegetables; unpasteurized dairy products; and ice and tap water) and travel to certain destinations, also have been identified.¹⁵⁵ Other authors previously categorized destinations by high, intermediate, and low levels of risk for acquiring traveler's diarrhea. Destinations generally considered to have the highest associated risk for contraction of traveler's diarrhea include most of Asia, Africa, Mexico, and Central and South America; destinations with intermediate risk include Eastern Europe, South Africa, and some of the Caribbean islands; and low-risk travel destinations include countries in North America, Northern and Western Europe, Australia, New Zealand, and Japan.⁴³ The location of food preparation also is a recognized risk factor for acquiring traveler's diarrhea, with a higher risk shown for travelers eating from street vendors and in local restaurants and a lower risk in luxury hotels and private homes. Although fewer data on traveler's diarrhea in children are available, children (especially toddlers) are probably more vulnerable to foodborne and waterborne pathogens for many reasons, including their propensity to touch multiple surfaces and to mouth objects. Of note, one study found that only 40% of parents said that they had practiced dietary prevention measures consistently and that only 5% reported using oral rehydration solutions (the mainstay of treatment of diarrhea in children).¹⁴²

Preventive Counseling for Traveler's Diarrhea

Counseling parents of pediatric travelers about appropriate preventive behavior to avoid traveler's diarrhea and anticipatory guidance to ensure successful management of diarrhea is an important aspect of the pretravel

assessment. Rotavirus vaccine and hepatitis A vaccine should be administered before travel if indicated, and cholera and typhoid vaccines should be considered if appropriate, as discussed earlier. However, adherence to hygiene measures and food and beverage precautions are the most important aspects of prevention.

Food and Beverage Precautions

The most important aspect of preventive counseling for parents of pediatric travelers is appropriate food and beverage precautions. In addition to preventing the diarrheal diseases already listed, compliance with food and water precautions also will decrease the risk for contracting other foodborne diseases, such as hepatitis A. Parents should be counseled that in areas where chlorinated tap water is not available or where hygiene and sanitation are poor, tap water (including ice cubes) should be considered contaminated and hence should be avoided. In addition, travelers also should be advised to avoid brushing their teeth with tap water. Breastfeeding, boiled or bottled water, and bottled carbonated beverages are recommended as typically safe beverages for children; powdered drink mixes made with boiled water (e.g., formula or tea) also generally can be considered safe. Parents should dry wet cans and bottles before opening and wipe drinking surfaces clean before serving.¹⁰⁴

In areas where access to bottled water is poor, water may be boiled for 1 minute (or for 3 minutes at altitudes above 2000 m [6562 ft]). These procedures will kill bacterial, parasitic, and viral pathogens. Chemical disinfection with halogens (iodine or chlorine) is an alternative method for water treatment when the water cannot be boiled; however, some common waterborne parasites, such as *Cryptosporidium*, are poorly inactivated by iodine disinfection, even after extended contact time. Chlorine also can be used for chemical disinfection, but its germicidal activity varies with pH, temperature, and organic content of the water; therefore it can provide less consistent levels of disinfection in many types of water. Thus chemical disinfection with iodine or chlorine should be supplemented with filtration to remove these organisms. However, chlorine dioxide, which is more potent than equivalent doses of chlorine, is effective against all waterborne pathogens, is simple to use, and is available in liquid or tablet form.⁴⁰ Tablets for water disinfection are available at pharmacies, sporting goods stores, and camping outfitters. Ultraviolet (UV) light is effective against all waterborne pathogens. Some portable devices are available; however, clear water is required to ensure that the UV rays can reach the pathogens in the water. Portable filters are available and provide various degrees of protection against microbes. Reverse-osmosis filters afford protection against viruses, bacteria, and protozoa, but they are large and expensive, and the small pores can be plugged by cloudy or muddy water. Microstrainer filters with pore sizes in the 0.1- to 0.3- μ m range can remove bacteria and protozoa from drinking water, but they do not remove viruses. To kill viruses, parents using microstrainer filters should be advised to chemically disinfect water with iodine after filtration. Data are inadequate at present to evaluate the efficacy of specific brands or models of filters, and therefore the CDC cannot recommend specific brands or models of filters most likely to remove bacteria, viruses, and parasites.⁴³

Parents of pediatric travelers also should be counseled on the importance of advance planning for food and beverage items, especially for infants and young children. Breastfeeding infants are considered relatively safe from contracting traveler's diarrhea because they are not exposed to local food and water; therefore traveling mothers should be encouraged to continue breastfeeding for as long as practical. For infants receiving formula, formula concentrate and powdered forms are the most convenient for travel, but a clean water supply must be available or water must be boiled or chemically disinfected before preparation. For feeding toddlers and older children, the travel adage of "boil it, cook it, peel it, or forget it" applies. In general, unless beverages and food come from a can or can be completely cooked or peeled, they should be considered unsafe (including raw fruits and vegetables). Travelers should avoid unpasteurized dairy products, including cheese and ice cream. In addition, travelers should be advised not to consume raw seafood, shellfish, and meats. Freshly prepared steaming hot food, breads and cereals, hot pasta (including rice and noodles), and

well-cooked meat or fish generally can be considered safe for consumption. Bringing crackers and peanut butter is a good suggestion for parents of hungry children when the availability of safe foods is uncertain. The incidence of traveler's diarrhea in children also can be reduced potentially by advising parents to encourage or supervise frequent hand washing, including the use of alcohol-based hand sanitizer, and to try to prevent children from placing objects in their mouths.

Some species of fish and shellfish can contain poisonous biotoxins, such as ciguatera and scombrototoxin, even when they are well cooked. Ciguatera poisoning is a potential risk in all subtropical and tropical regions of the West Indies and the Pacific and Indian oceans where the implicated fish are consumed; such fish include barracuda, red snapper, grouper, amberjack, and sea bass. Symptoms of ciguatera poisoning include gastroenteritis and neurologic manifestations such as dysesthesias and weakness. Scombroid poisoning occurs in tropical and temperate regions and is caused by high levels of histidine in the flesh of fish such as bluefin, yellowfin tuna, mackerel, bonito, mahi-mahi, herring, amberjack, and bluefish; if improperly refrigerated, histidine is converted to histamine, which can cause flushing, headache, nausea, vomiting, diarrhea, and urticaria.⁴³

Managing Traveler's Diarrhea in Children

Adults traveling with children should be counseled about the signs and symptoms of dehydration and the proper use of WHO oral rehydration solution (ORS). Immediate medical attention is required for an infant or young child with diarrhea who has signs of moderate to severe dehydration, bloody diarrhea, temperature higher than 38.5°C (>101.5°F), or persistent vomiting. ORS should be provided to the infant by bottle or spoon while medical attention is being obtained.

The greatest risk to the infant with diarrhea and vomiting is dehydration. Fever or increased ambient temperature increases fluid losses and speeds dehydration. Parents should be advised that dehydration is best prevented and treated by use of ORS, in addition to the infant's usual food. Rice-based and other cereal-based ORSs, in which complex carbohydrates are substituted for glucose, also are available and may be more acceptable to young children. Adults traveling with children should be counseled that sports drinks, which are designed to replace water and electrolytes lost through sweat, do not contain the same proportions of electrolytes as those of the solution recommended by WHO for rehydration during diarrheal illness.

ORS packets are available at stores or pharmacies in almost all developing countries as well as most pharmacies in the United States. ORS is prepared by adding one packet to boiled or treated water. Travelers should be advised to check packet instructions carefully to ensure that the salts are added to the correct volume of water. ORS should be consumed or discarded within 12 hours if it is held at room temperature or 24 hours if it is kept refrigerated. A dehydrated child will drink ORS avidly; travelers should be advised to give it to the child as long as the dehydration persists. An infant or child who vomits the ORS usually will keep it down if it is offered by spoon, oral syringe, or straw in frequent small sips.^{41,112,153}

Children weighing less than 10 kg who have mild to moderate dehydration should be administered 60 to 120 mL (2–4 oz) of ORS for each diarrheal stool or vomiting episode. Children who weigh 10 kg should receive 120 to 240 mL (4–8 oz) of ORS for each diarrheal stool or vomiting episode. Severe dehydration is a medical emergency that usually requires administration of fluids by intravenous or intraosseous routes.^{43,72,111,151}

Travelers should be advised to give ORS to the child as long as the dehydration persists. As dehydration lessens, the salty-tasting ORS solution may be refused, and another liquid can be offered. Severely dehydrated children, however, often will be unable to drink adequately. Severe dehydration is a medical emergency that usually requires administration of fluids by intravenous or intraosseous routes.

Breast-fed infants should continue nursing on demand. Formula-fed infants should continue their usual formula during rehydration. They should receive a volume sufficient to satisfy energy and nutrient requirements. Lactose-free or lactose-reduced formulas usually are unnecessary. Dilution of formula may slow resolution of diarrhea and is not recommended. Older infants and children receiving semisolid or solid foods

should continue to receive their usual diet during the illness. Recommended foods include starches, cereals, yogurt, fruits, and vegetables. Foods that are high in simple sugars, such as soft drinks, undiluted apple juice, gelatins, and presweetened cereals, can exacerbate diarrhea by osmotic effects and should be avoided. In addition, foods high in fat may not be tolerated because of their tendency to delay gastric emptying. The practice of withholding food for 24 hours or longer is inappropriate. Early feeding can decrease changes in intestinal permeability caused by infection, reduce illness duration, and improve nutritional outcome. Highly specific diets (e.g., the BRAT [bananas, rice, applesauce, and toast] diet) frequently have been recommended; however, similar to juice-centered and clear-fluid diets, such severely restrictive diets used for prolonged periods can result in malnutrition and should be avoided.¹¹¹

Parents should be particularly careful to wash hands well after changing diapers of infants with diarrhea to avoid spreading infection to themselves and other family members.

Oral syringes available in most pharmacies for oral medications can be useful for the administration of ORS and can be included as part of the traveler's health kit for young children. Straws also can be useful for older children.

Bismuth subsalicylate (BSS), which is the active ingredient in Pepto-Bismol, can be used to prevent travelers' diarrhea in children 12 years of age and older. BSS can cause blackening of the tongue and stool and may cause nausea, constipation, and, rarely, tinnitus. BSS should be avoided by travelers with aspirin allergy, renal insufficiency, and gout and by those taking anticoagulants, probenecid, or methotrexate. In travelers taking aspirin or salicylates for other reasons, the use of BSS may result in salicylate toxicity. Because of the association between salicylates and Reye syndrome, BSS is not generally recommended to treat diarrhea in children younger than 12 years; however, some clinicians use it off-label, with caution in certain circumstances. Caution should be taken in administering BSS to children with viral infections, such as varicella or influenza, because of the risk for Reye syndrome. BSS is not recommended for children younger than 3 years. Studies have not established the safety of BSS use for periods longer than 3 weeks.⁴⁰ Insufficient data are available at this time to recommend the use of probiotics for the prevention of travelers' diarrhea in children.^{43,75}

The use of antimotility agents (e.g., loperamide [Imodium] or diphenoxylate and atropine [Lomotil]) in children younger than 2 years is not recommended and should be avoided because it can lead to serious adverse events, including toxic megacolon and central nervous system depression.¹⁰⁸ Because overdose of these types of drugs can be fatal, they should be used with extreme caution in children. Side effects of these drugs in adults include opiate-induced ileus, drowsiness, and nausea. Lomotil has been associated with fatal overdoses and other severe complications, including coma and respiratory depression. Antinausea medications, such as promethazine and prochlorperazine, are not recommended routinely. They are contraindicated for use in children younger than 2 years. Fatal respiratory depression in children has been reported with use of promethazine. Children with an acute illness, including gastroenteritis and dehydration, are more susceptible than are adults to neuromuscular reactions, especially dystonias, associated with prochlorperazine. The extrapyramidal side effects associated with these medications can be confused with symptoms of other undiagnosed primary diseases associated with vomiting, such as Reye syndrome. These medications should not be prescribed routinely for empirical treatment of children with possible traveler's diarrhea. Adults traveling with children should be fully counseled about the indications, dosage, frequency, and possible side effects if these medications are prescribed.^{43,111}

Antibiotics

Prophylactic antibiotics are not recommended for most travelers. Many clinicians will prescribe antibiotics to be administered as empirical self-treatment. Trimethoprim-sulfamethoxazole was used previously for empirical treatment of traveler's diarrhea in children; however, widespread drug resistance has reduced its effectiveness, and it is no longer routinely recommended. Fluoroquinolones are used frequently for the empirical treatment of traveler's diarrhea in adults. In children,

the American Academy of Pediatrics suggests some special circumstances for fluoroquinolone use, including the treatment of gastrointestinal infection caused by multidrug-resistant *Shigella* spp., *Salmonella* spp., *V. cholerae*, or *Campylobacter jejuni*.⁶⁷ For young adults 19 years and older, the fluoroquinolones are generally prescribed as 1- to 3-day regimens. Clinicians should be aware that fluoroquinolone resistance in gastrointestinal organisms has been reported from some countries, particularly in Southeast Asia.

Azithromycin has been found to be as effective as fluoroquinolones in treating traveler's diarrhea in adults.¹ In adults, some clinicians prescribe azithromycin as a single dose, which has been found to be highly effective. In children, most clinicians prescribe 10 mg/kg (maximum, 500 mg) for 3 days for empirical treatment of suspected *Shigella*, *Campylobacter*, and certain *E. coli* infections. Flavored oral suspension of azithromycin is available. The suspension does not require refrigeration; however, it should be used within 10 days of mixing. The non-reconstituted form of azithromycin has a longer expiration period. In certain circumstances, the non-reconstituted form can be provided with clear instructions for preparation and may be useful for children traveling for more than 10 days.

PREVENTION OF OTHER INFECTIOUS DISEASES IN PEDIATRIC TRAVELERS

Because the epidemiology of many diseases is evolving, prevention hinges on the clinician being knowledgeable about information on current outbreaks and risk in planned travel destinations, evaluating risk based on planned activities and the season of travel, and providing appropriate counseling and vaccination, if available. Information about specific infectious disease risks can be obtained from numerous sources listed in the section on international travel information resources. More detailed information about specific vaccinations is included in the section on vaccination for international travel.

Middle East coronavirus syndrome (MERS) was first reported in September 2012 and should be considered in individuals who have a syndrome of pneumonia and travel to the Arabian Peninsula or neighboring countries within the past 14 days. Common symptoms include fever (temperature >38°C [100.4°F]), cough, and shortness of breath, often leading to severe pneumonia and/or acute respiratory distress syndrome. Patients can also have acute kidney injury, gastrointestinal symptoms (anorexia, nausea, vomiting, abdominal pain), pericarditis, and disseminated intravascular coagulation.⁴⁸ There is one published description of MERS-CoV infection of children infected with MERS. In this series, the median age of patients was 13 years (range, 2–16 years). Nine children did not have symptoms, one patient died, and one patient who had symptoms recovered. Both patients with symptoms had underlying conditions.¹³⁰

Avian influenza A (H5N1) has become a zoonotic infection affecting regions of Asia, Africa, and the Middle East. Between 2003 and July 6, 2012, the WHO reported 607 human cases and 358 deaths caused by avian influenza from 15 countries, primarily from Indonesia, Vietnam, Egypt, China, Cambodia, and Thailand. Most of these cases were associated with direct contact with infected poultry.^{59,124} Risk to travelers is low. However, clinicians should obtain up-to-date information about affected countries and counsel travelers going to those areas. Persons visiting areas with reports of outbreaks of H5N1 among poultry or of human H5N1 cases can reduce their risk for infection by (1) avoiding direct contact with poultry, including touching well-appearing, sick, or dead chickens; (2) avoiding poultry farms and bird markets; (3) avoiding handling surfaces contaminated with poultry feces or secretions; (4) practicing frequent and careful hand washing; and (5) consuming all foods from poultry, including eggs and poultry blood, only if they have been thoroughly cooked. Because influenza viruses are destroyed by heat, the cooking temperature for poultry meat should be 74°C (165°F).⁵⁹

African trypanosomiasis (sleeping sickness), a parasitic infection transmitted by the bite of a tsetse fly, occasionally has been reported in travelers, including children. Infection can result in severe neurologic sequelae and is 100% fatal if untreated.⁵⁶ Infection is caused by two species of *Trypanosoma brucei*: *T. brucei rhodesiense*, which is found in

eastern and southeastern Africa (primarily Tanzania, Uganda, Malawi, and Zambia), and *T. brucei gambiense*, which is found predominantly in central Africa and limited areas of West Africa. Most infections in US residents are caused by *T. brucei rhodesiense* and occur among travelers to East Africa game parks. In 2001, significant increases in cases were reported among US and European travelers to game parks in Tanzania and Kenya. Between 1967 and 2000, an imported case occurred on average every 1 to 2 years; however, in 2001, seven cases were reported in US travelers.^{17,31,76,78,131-134} Travelers should use insect repellent and long-sleeved clothing in neutral colors of medium-weight material because tsetse flies are attracted to bright or dark clothes and can bite through lightweight clothing.⁴³

Schistosomiasis, another parasitic infection caused by flukes that live part of their life cycle in fresh-water snail hosts, affects more than 200 million people worldwide. Schistosomiasis has been reported in travelers to endemic areas of Africa, Asia, South America, and the Caribbean who participated in high-risk activities such as swimming and wading in fresh water.^{43,47,62,68} Most travel-associated infections occur among travelers to sub-Saharan Africa. Because most acute infections are asymptomatic, preventive counseling is critical. While in schistosomiasis-endemic areas, children should not swim in fresh, unchlorinated water such as lakes or ponds.⁴³

More than 9 million new tuberculosis (TB) cases and 2 million TB-related deaths occur annually worldwide. A rate of tuberculin skin test seroconversion of 1.8% was reported among travelers to areas endemic for TB.⁶⁵ Of 357 travelers to the Hajj for pilgrimage, 10% had evidence of seroconversion when tested with use of QuantiFERON, a whole-blood assay for TB antigens.¹⁷² Multidrug-resistant TB has been increasing in incidence worldwide. Cases of extensively drug-resistant TB have been reported from several countries, including Estonia, Latvia, Lesotho, Peru, the Philippines, South Africa, Swaziland, and the United States.^{177,178} Travelers who may have prolonged exposure to TB should have two-step tuberculin skin test (TST) or a single interferon- γ release assay (IGRA), either the QuantiFERON TB test (Gold or Gold In-Tube versions) or T-SPOT TB test, before leaving the United States. If the predeparture test is negative, a single TST or IGRA should be repeated 8 to 10 weeks after returning from travel. IGRA is preferred for children who have received bacille Calmette-Guérin (BCG) vaccine.⁴³ According to reports, US children who had traveled to countries with a high prevalence of TB within the previous 12 months were 3.9 times more likely to have positive tuberculin skin test results than were children who lived in the same US areas but had not traveled.¹¹⁹ BCG vaccine is a live vaccine prepared from attenuated strains of *Mycobacterium bovis*; BCG is used primarily in young infants to prevent disseminated and other forms of life-threatening disease caused by TB, such as tuberculous meningitis. BCG is recommended by the WHO for administration at birth. Vaccination of a young pediatric traveler (non-HIV infected and with a negative tuberculin skin test response) might be considered if long-term stay (e.g., children of missionaries or expatriates) is planned in a country with a high prevalence of TB, particularly multidrug-resistant or extensively drug-resistant TB, and prolonged contact with persons with active TB is thought to be a potential problem.^{4,5,7} BCG vaccine can be obtained from the Canadian subdivisions of Sanofi Pasteur (<http://www.sanofipasteur.ca>).

Tick-borne encephalitis is transmitted primarily by the bite of *Ixodes* ticks. It also can be transmitted by the ingestion of unpasteurized dairy products from infected livestock. Transmission occurs during the summer months in western and central Europe, Scandinavia, and parts of the former Soviet Union. Russia has the highest incidence. Most cases occur from April through November, when ticks are most active.⁴³ Travelers to affected areas should use measures to avoid tick bites and avoid consuming unpasteurized dairy products. Persons who will be traveling for longer than 3 weeks in endemic rural areas or travelers who will be engaging in high-risk activities, such as camping, should be considered for vaccination. The vaccine is not available in the United States but can be obtained in Europe and Canada.⁴³

Adventure travel can increase the risk for acquiring a variety of infectious diseases. Examples of recent outbreaks or cases of unusual pathogens affecting adventure travelers include fungal organisms (e.g., histoplasmosis and coccidioidomycosis), leptospirosis, and leishmaniasis.

Histoplasmosis is a fungal infection acquired by the inhalation of spores, usually through exposure to bat, bird, or chicken droppings in barnyards and caves. The organism is endemic in the United States, Latin America, eastern Asia, parts of Europe, Africa, and Australia. Coccidioidomycosis, a fungal infection associated with the inhalation of organisms in soil from high-risk areas, is endemic in the southwestern part of the United States and Latin America. Both infections can cause a spectrum of illness from asymptomatic infection to acute pulmonary infection to severe, disseminated disease, especially in immunocompromised persons. Several outbreaks of histoplasmosis have been reported in groups of US visitors who entered a cave with bats in Costa Rica,²² Ecuador,^{164,176} Peru,²¹ and Nicaragua.¹⁷⁰ More than 200 college students became infected with histoplasmosis during a spring break trip to Acapulco, Mexico.^{31,141,180} Two outbreaks of coccidioidomycosis have been reported in youth missionary groups involved in construction work in Mexico.^{20,24} Most of these fungal outbreaks have two common features: high-risk group activities and high attack rates, even in young, nonimmunocompromised individuals. Because no vaccine is available, prevention involves counseling travelers to avoid exposure or to use special masks for high-risk individuals who cannot avoid exposure.³²

Leptospirosis is a zoonotic infection transmitted by exposure to water or soil contaminated with organisms excreted by domestic and wild animals. Outbreaks have been reported in white-water rafters in Costa Rica²³ and in athletes from 26 countries who participated in the Eco-Challenge multisport expedition race in Borneo, Malaysia, in 2000.^{26,30} Because no vaccine against leptospirosis exists, persons engaging in high-risk activities with exposure to recreational water activities or exposure to contaminated surface waters and soil should be counseled to avoid exposure to water that may be contaminated or to wear protective clothing, especially footwear, and to cover cuts and abrasions with occlusive dressings. They should avoid contact with, submersion in, or swallowing potentially contaminated water. The CDC recommends that persons engaging in high-risk activities consider the use of doxycycline (4 mg/kg per dose, to a maximum of 200 mg/kg per dose every week), begun 1 to 2 days before exposure and continuing through the period of exposure for prophylaxis; doxycycline should not be used routinely for children younger than 8 years.⁴³ Travelers at increased risk for leptospirosis and in need of malaria chemoprophylaxis should consider using doxycycline for both indications.

Leishmaniasis, a parasitic infection transmitted by the bite of a sandfly, can lead to cutaneous or visceral infection. It has been reported in students who traveled to the rainforest in Costa Rica and other travelers.^{94,96,129,174} The appropriate use of insect repellent and other personal protection measures against sandfly bites is the only prevention tool available.

Finally, studies of sexual practices among travelers have shown that 5% to 50% of short-term travelers engage in casual sex while abroad; 40% to 60% of long-term travelers have reported engaging in casual sex while abroad.^{127,144,145} A study of British travelers reported that 18.6% had had new sexual partners, two-thirds of those who were sexually active did not use condoms on every occasion, and 5.7% contracted STIs.¹⁵⁵ Adolescents should be counseled about the risks for and prevention of STIs, hepatitis B, and HIV infection associated with sexual contact, sharing needles, or receiving acupuncture or tattoos. Patients should be asked about high-risk behaviors including sex without condoms, injection drug use, and sex while using drugs. Preexposure prophylaxis (PrEP) for HIV should be offered if deemed necessary. Before giving PrEP, patient should have HIV testing, a serum creatinine level and if female, a pregnancy test. At this point, the most widely studied medication used for PrEP two oral antiretroviral medications (tenofovir and emtricitabine) coformulated as a single pill (Truvada) taken once daily. Based on pharmacokinetic data, patients should initiate the drug 1 week before high-risk activity for a male patient and 3 weeks before high-risk activity for a female patient and continue PrEP for 1 month afterward.¹⁵² Testing for STIs should be offered on return from the trip.

GENERAL TRAVEL HEALTH COUNSELING FOR CHILDREN

During the pretravel assessment, the clinician should provide the parents with general advice and preventive counseling to avoid health risks and

injuries in children. Simple personal protection measures can prevent children from incurring many types of travel-associated injuries and conditions. One of the most common skin conditions reported by travelers is sunburn. To prevent sunburn and the subsequent risk for skin malignant neoplasms later in life, children should avoid sun exposure during peak hours and use sunscreen appropriate for the child's age. When sunscreen and insect repellent are used concomitantly, the sunscreen should be applied first. There is no evidence that air travel exacerbates the symptoms or complications associated with otitis media.⁷¹ Travel to different time zones, "jet lag," and schedule disruptions can disturb sleep patterns in infants and children, as well as adults.⁴³

Motor vehicle collisions, injuries, and drownings pose a great risk for morbidity and mortality among international travelers.^{43,144} Vehicle-related incidents are the leading cause of death in children who travel. While traveling in automobiles and other vehicles, children shorter than 4 feet, 9 inches in height should be restrained in age-appropriate car seats or booster seats, as described earlier. In general, children are safest traveling in the rear seat; no one should ever travel in the bed of a pickup truck. Families should be counseled that in many developing countries, cars may lack front or rear seat belts. Parents traveling with infants or young children should be advised to bring their own child safety restraint seats for use during travel. Night driving can be more hazardous, especially outside urban areas in developing countries, and should be avoided.⁴³ Use of a helmet is imperative for bicycle travel. Fire injuries can be prevented by advising parents to inquire whether hotels have smoke detectors and sprinkler systems (they also may consider bringing their own smoke detector). Conditions at hotels and other lodging may not be as safe as those in the United States, and accommodations should be carefully inspected for exposed wiring, pest poisons, paint chips, or inadequate stairway or balcony railings.⁴³ Drowning is the second leading cause of death in young travelers. Children may not be familiar with hazards in the ocean or in rivers. Swimming pools may not have protective fencing to keep toddlers from falling into the pool. Close supervision of children around water is essential. Appropriate water-safety devices such as life vests may not be available abroad, and families should consider bringing these from home. Parents and children participating in boating activities should be counseled to be aware of weather conditions and forecasts, and parents should be advised that an adult should accompany children at all times when swimming. Personal floatation devices should be used when boating or water-skiing, regardless of the distance to be traveled or swimming ability.¹⁵⁰ Swimming in contaminated water can result in skin, eye, ear, and some intestinal infections; for prevention of infectious diseases, generally only pools that contain chlorinated water can be considered safe. Parents also should be advised that swimming in fresh-water lakes and streams in developing countries carries a risk for contracting schistosomiasis, leptospirosis, and primary amebic meningoencephalitis.⁴³ In saltwater bodies, biting and stinging fish, corals, and jellyfish also can be a risk. In general, children should wear covered footwear rather than sandals, including when wading on reefs and swimming.^{43,150} Children should avoid walking barefoot, particularly in rural areas, to prevent cutaneous larva migrans, hookworm, and *Strongyloides* infections. Children are more likely than adults to have contact with soil or sand and therefore may be exposed to diseases caused by infectious stages of parasites present in soil, including ascariasis, hookworm infestation, cutaneous or visceral larva migrans, trichuriasis, and strongyloidiasis. Children and infants should wear protective footwear and play on a sheet or towel rather than directly on the ground. Clothing should not be dried on the ground. When traveling in countries with a tropical climate, clothing or diapers dried in the open air should be ironed before use to prevent infestation with fly larvae. Parents of pediatric travelers, especially to areas endemic for rabies, should be reminded to warn children that they should not attempt to pet, handle, or feed domestic or wild animals (including monkeys). Travelers also should avoid snakes because most bites are the direct result of handling, harassing, or trying to kill snakes.⁴³

Travelers to high-altitude destinations should be counseled about the risk and prevention of altitude illness, including acute mountain sickness, high-altitude cerebral edema, and high-altitude pulmonary edema. Altitude sickness generally occurs at 2500 to 2700 m (8000–9000

ft), and acclimatization generally takes 3 to 5 days. Susceptibility and resistance are genetic traits, and no screening tests are available to predict risk. Children and adults are equally susceptible. Travelers to high-altitude destinations should be advised to ascend gradually, if possible, and those travelers going to destinations higher than 8000 to 9000 ft should be advised to acclimate at 8000 to 9000 ft for a few days before moving to higher altitudes. For higher altitudes, travelers should move sleeping altitude no higher than 500 m (1600 ft) per day and to plan on spending an extra day for acclimatization for every 1000 m (3300 ft), if possible. For abrupt ascent, pediatric travelers may require acetazolamide, prescribed as 2.5 mg/kg per dose every 12 hours, up to the standard adult dose of 125 mg twice per day. Travelers should begin acetazolamide 1 day before ascent and continue for the first 2 days at altitude. Dexamethasone is generally reserved for treatment of altitude illness.⁴³

PEDIATRIC TRAVELER'S HEALTH KIT

Children traveling to developing countries may have unique exposures, particularly if they are traveling to remote locations or will have close contact with other children. Depending on the travel itinerary, children may need prescriptions for malaria chemoprophylaxis, antibiotic for self-treatment of travelers' diarrhea, and medication to prevent high-altitude sickness. Consideration should be given to inclusion of the following medications as part of the traveler's health kit: rectal preparations (suppositories) of selected medications, such as acetaminophen; topical treatments for lice and scabies for pediatric travelers to developing countries who may have extensive contact with local children; and a topical antibiotic, such as mupirocin, for bacterial skin infections.^{43,117} Children with a history of anaphylaxis or serious allergic reactions should have a sufficient number of epinephrine pens and antihistamines in tablet or liquid form. Any medications purchased abroad should be obtained from a reliable pharmacy because of concern about counterfeit drugs, especially in developing countries. Adults accompanying these children and teenagers should consider obtaining basic first aid and safety training before departure. Although air travel is safe for healthy newborns, infants, and children, a few issues should be considered in preparation for travel. Children with chronic heart or lung problems may be at risk for hypoxia during flight, and a physician should be consulted before travel. Insurance coverage for illnesses and accidents while abroad should be verified before departure.⁷¹ Consideration should be given to purchasing special travel insurance for airlifting or air ambulance to an area with adequate medical care.⁴³

INTERNATIONAL TRAVEL INFORMATION RESOURCES

One of the most important functions a clinician can fulfill in preparing a pediatric patient and parents for international travel is to provide up-to-date and accurate travel health information and recommendations for preventing illness. Many varied sources of information are available, including software packages and databases designed specifically for use in travel medicine and pretravel care.^{84,110} Increasingly, the Internet and computer-based travel resources are being used by practitioners and consumers alike because they provide current information to appropriately and effectively counsel and treat international travelers. Two reviews have provided comprehensive summaries of travel medicine resources.^{84,110} Table 232.4 is a summary of selected travel health resources that can be useful for providing health care professionals and parents with essential information on health risks in specific travel destinations (including endemic or epidemic diseases) and current travel health recommendations (including immunizations and chemoprophylaxis). Travelers also should be aware of the need for health insurance and emergency evacuation coverage during travel and medical assistance in the event of a travel-related illness; a variety of companies offer these services, and travelers should investigate options before making any purchases. This summary is not meant to be comprehensive; because resources are constantly changing, clinicians are advised to review and to compare sites for availability and updated information and recommendations.

TABLE 232.4 International Travelers' Health Information, Recommendations, and Outbreak Notices

Resource	Contact Information	Information and Services Provided
Centers for Disease Control and Prevention (CDC) Travelers' Health Information Destination-Specific Information	http://wwwnc.cdc.gov/travel/	US travelers' health recommendations by destination region and country, including malaria chemoprophylaxis and vaccinations; links to other sites, travel health warnings, advisories, and outbreak notices

Infectious Disease Considerations in International Adoptees and Refugees

Mary Allen Staat

Each year thousands of children immigrate to the United States to begin a new life (Fig. 233.1). The focus of this chapter will be on two groups of immigrants—refugees and internationally adopted children. Refugees are noncitizen immigrants who are unable or unwilling to return to their country of origin because of persecution or fear of persecution.

Internationally adopted children are immigrants who are classified as orphans; however, most of these children are not truly orphaned, but have been abandoned by or separated from both parents.¹¹¹ These children generally will be given United States citizenship as they arrive or shortly after they arrive in the United States to join their new families.

FIG. 233.1 A group of internationally adopted children.

In 2015, a total of 69,920 refugees arrived in the United States.¹¹¹ Of these, 80% came from just six countries: Burma (26%), Iraq (18%), Somalia (13%), Democratic Republic of the Congo (11%), Bhutan (8%), and Iran (4%). Although these are the most prevalent countries, refugees have come to the United States from countries all around the world, with the exception of northern Europe, Australia, New Zealand, and Canada. Of refugees immigrating to the United States in 2015, 43% were younger than 20 years and 48% were female. The ages of the children were fairly evenly distributed—younger than 5 years (26%), 5 to 9 years (27%), 10 to 14 years (24%), and 15 to 19 years (23%). Only 1% of refugee children were younger than 1 year.

In recent decades, international adoption has been a popular way to build families. Since 1999, more than 261,000 children have been internationally adopted to families in the United States.¹²⁰ The peak of international adoptions was in 2004, with 22,990 children immigrating to the United States; 83% of children came from just five countries: China (31%), Russia (26%), Guatemala (14%), South Korea (8%), and Kazakhstan (4%).¹²⁰ However, since 2004, a dramatic decline has occurred in the number of adoptions, and the countries where children are adopted from are far more diverse. In 2015, only 5648 children were adopted internationally, with 81% of children coming from 11 countries: China (42%), Ethiopia (6%), South Korea (6%), the Ukraine (5%), Uganda (4%), Bulgaria (3%), Latvia (3%), the Democratic Republic of the Congo (3%), Colombia (3%), Nigeria (3%) and the Philippines (3%).¹²⁰ Several countries that once allowed adoption, such as Romania, Vietnam, Cambodia, and Guatemala, are now closed to adoptions or have dramatically decreased the number of international adoptions from their countries. For example, in 2008, the largest numbers of adopted children were from Guatemala, with 4123 adoptions. In contrast, after the United States stopped processing Guatemalan adoptions, only 13 children were adopted from Guatemala in 2015.¹²⁰ In addition, there has been a change in the medical needs of internationally adopted children. In recent years, China has shifted to primarily referring children with special needs such as congenital heart disease, cleft lip and palate, limb deficiencies, anorectal malformations, spina bifida, and cerebral palsy, whereas in prior years, most children referred to families from China were healthy infants without known medical conditions.

Other demographic features have changed in international adoption as well. In 2015, 50% of internationally adopted children were female, 54% of children were younger than 5 years, and 1% were younger than 1 year at the time of adoption.¹²⁰ In contrast, in 2004, 65% of adopted children were girls, mainly because of the large number of girls available in China. Children were also much younger, with 86% of children younger than 5 years and 41% younger than 1 year.¹²⁰ With the arrival of older children, health care providers need to be aware that these children will have an increased risk for malnutrition, infectious disease exposures, unmet medical needs, and psychological traumas that often results in a more difficult transition to joining their families.

Children available for international adoption generally have resided all or most of their lives in orphanages before coming to the United States. The exception is South Korea and Guatemala, where nearly all children were placed in foster care until their adoption. In more recent years, some children from China have also been placed with foster families until adopted.

Because refugees and internationally adopted children come from resource-poor countries, physicians and other health care providers need to be aware of the global prevalence of infectious diseases that are seen less commonly in native-born North Americans. Both refugees and internationally adopted children are at increased risk for common infectious diseases such as tuberculosis (TB), intestinal parasites, dermatologic infections, and infestations. In addition, in countries where resources are few and infrastructure is limited for screening and prevention programs for hepatitis B, hepatitis C, human immunodeficiency virus (HIV), and syphilis, the prevalence is higher than in the United States.

Although many similarities exist in the infectious disease considerations for refugees and internationally adopted children, several important differences are seen.^{6,10,12,35,37} Refugee and internationally adopted children differ in terms of the general medical screening they receive before their arrival to the United States.^{10,137} Most refugees undergo organized screening evaluations before emigration visas are issued. Children have predeparture screening and a physical examination, and, depending on their country of departure, they may receive predeparture treatment for malaria, intestinal parasites, or tissue parasites. In contrast, only adoptees from certain countries with high rates of TB, such as China and Ethiopia, have been required to undergo this organized screening procedure for TB. Second, because medical screening for refugees is usually sponsored by responsible medical organizations, results of testing are typically accurate. In internationally adopted children, medical testing may be incomplete and is typically done shortly after birth or on entrance to the orphanage. However, families should expect to receive results for HIV, syphilis, and hepatitis B surface antigen testing with their referral information. For some countries, such as Ethiopia, HIV polymerase chain reaction (PCR) and hepatitis C test results also are provided. For Russian referrals, hepatitis C testing is often done as well. Although the reliability of testing done in the child's birth country has been a concern in the past, in recent years the testing has generally proved to be accurate when repeated in the United States. Third, preventive measures such as immunizations, vitamin supplementation, and dental care are provided for most refugee children while still in refugee camps; in adoptees, no standard approach is followed in the provision of these measures from country to country or even within a given country. Differences also exist in the types of infectious diseases and risks for acquiring these diseases in refugee children in contrast to internationally adopted children. Although both groups are susceptible to a variety of infectious agents, because the countries of origin and the living conditions differ, refugee children are more likely to have been exposed to infections such as typhoid fever, malaria, filariasis, flukes, and schistosomiasis, which are less commonly seen in internationally adopted children from countries outside of Africa.

Health care professionals will inevitably have the opportunity to provide care for these children as they immigrate to the United States and should therefore be knowledgeable of the infectious disease issues they may encounter and the need for screening for infectious diseases in these populations.

OVERALL EVALUATION

Because of the predominance of infectious diseases in resource-poor countries, recommendations for screening tests in refugees and internationally adopted children have been weighted toward infectious disease processes; thus this will be the focus of this chapter. It is important, however, that the initial assessment include all aspects of general health, including evaluation of growth and development and vision, hearing, and dental evaluations.^{6,10,12,35,37} For internationally adopted children, several others tests are recommended, including testing for blood lead concentration, complete blood cell count with red blood cell indices, and differential of white blood cells to evaluate for eosinophilia,

TABLE 233.1 Infectious Disease Screening for Refugee and Internationally Adopted Children

Condition or Test	Refugee Children	Internationally Adopted Children
Hepatitis A Virus (Acute Infection)		
Hepatitis A IgM antibody	Not recommended	All
Hepatitis B Virus		
Hepatitis B surface antigen (HBsAg)	All	All ^a
Hepatitis B surface antibody (anti-HBs)	All	All ^a
Hepatitis B core antibody (anti-HBc)	All	All ^a
Hepatitis C Virus		
Hepatitis C antibody	Some	All ^a
Syphilis		
Nontreponemal test (RPR, VDRL, or ART)	≥15 years	All
Treponemal test (TPPA, MHA-TP, or FTA-ABS)	Not recommended	All
Human Immunodeficiency Virus		
Human immunodeficiency virus 1 and 2 antibody	≥13 years	All ^a
Recommended	<13 years	
Tuberculosis		
Tuberculin skin test (TST)	All	All ^a
or		
Interferon-γ release assay	≥5 years	≥5 years
Intestinal Parasites		
Microscopic evaluation of stool for ova and parasites	All (2 specimens) ^b	All (3 specimens)
<i>Giardia intestinalis</i> and <i>Cryptosporidium</i> antigen	All (1 specimen) ^b	All (1 specimen)
Bacterial Enteric Infection		
In children with diarrhea: bacterial stool culture	All	All
Chagas (Endemic Areas)		
<i>Trypanosoma cruzi</i> serologic testing	All	All
Complete Blood Count	All	All
Eosinophilia With Negative Stool Ova and Parasite for Helminths		
<i>Strongyloides</i> serologic testing	All	All
<i>Schistosoma</i> serologic testing (endemic countries) ^c		
Lymphatic Filariasis (Endemic Areas)		
<i>Filaria</i> serology	All	≥2 years
Chagas (Endemic Areas)		
<i>Trypanosoma cruzi</i> serologic testing	All	All
Malaria Screening (Endemic Areas)		
Malaria polymerase chain reaction	All without pretreatment	Not recommended
Hematuria (Schistosomiasis)		
Urinalysis	All	Not recommended

^aConsider reassessing 6 months after arrival.

^bAll should be screened if there was no presumptive treatment before arrival to the United States; see guidelines for evaluation for intestinal parasites in refugees with presumptive treatment (<http://cdc.gov/immigrantrefugeehealth/guidelines/domestic/intestinal-parasites-domestic.html>).

^cSome experts recommend serologic testing regardless of whether eosinophilia is present.

ART, Automated reagin test; FTA-ABS, fluorescent treponemal antibody absorption; MHA-TP, microhemagglutination–*Treponema pallidum*; RPR, rapid plasma reagin; TPPA, *Treponema pallidum* particle agglutination; VDRL, Venereal Disease Research Laboratory.

glucose-6-phosphate dehydrogenase screening, hemoglobin electrophoresis, measurement of thyroid-stimulating hormone concentration, and examination for congenital anomalies (including fetal alcohol syndrome). Similar to adoptees, a complete blood count and a lead level are recommended for refugees. Additional tests, such as a urinalysis to determine whether there is hematuria (for schistosomiasis) and screening for sexually transmitted infections, are recommended. Mental health screening is encouraged if services are available.

Although many immigrant children may appear healthy on arrival, children should be evaluated by a health care professional within 2 weeks after arrival to ensure that their initial health care needs are addressed, initial screening is done, and a plan for receiving preventive services such as immunizations is initiated. Table 233.1 outlines the infectious disease screening tests recommended for refugee and internationally adopted children, and details for each condition are outlined in the following discussion.

INFECTIOUS DISEASE SCREENING

Viral Hepatitis

Hepatitis A

Virtually all people residing in resource-poor countries have contracted hepatitis A by early adulthood and have hepatitis A immunoglobulin G (IgG) antibodies.^{1,7,34} The prevalence of past hepatitis A infection varies by country and age. In a study examining the prevalence of acute and past hepatitis A infection in internationally adopted children, 1% of children had acute hepatitis A infection (positive hepatitis A IgM) on arrival to the United States and 29% had evidence of prior infection (positive total hepatitis A antibody).¹ In this study, the prevalence of prior infection increased with age; 13% of children younger than 2 years were immune, in contrast to 80% of children 12 to 17 years of age. The highest region-specific prevalence was in Africa (72%), and the lowest was in the Asia and Pacific Rim Region (17%).

Given the high prevalence of hepatitis A virus (HAV) in these countries, there is an ongoing risk for infection of children while in their country of origin. In internationally adopted children, children may be incubating HAV infection at the time of adoption and could transmit the virus to their adoptive families and others while in country or after arrival to the United States. Several cases have been reported of HAV transmitted from internationally adopted children to family members and close contacts.^{1,48,123,138} Therefore adoptive parents and any accompanying family members should be immunized against hepatitis A or have documented immunity to HAV infection before international travel to receive their child.^{1,7,17,31,47} It is also recommended that hepatitis A vaccine be administered before the arrival of the adoptee to all susceptible nontraveling people who plan to have close contact with an internationally adopted child from a country with high or intermediate hepatitis A endemicity.

In the United States, hepatitis A vaccine is recommended for all children 12 months of age and older.^{7,31} Hepatitis A vaccine is not routinely administered to children or adults in resource-poor countries. Because the prevalence of past HAV infection is high in these countries, antibody testing can be done to determine HAV immunity. Hepatitis A antibody testing (total or IgG) should be considered in children older than 1 year for both refugees and internationally adopted children to determine the need for this vaccine.^{9,10}

Infection with hepatitis A is often difficult to diagnose clinically in children; as many as 90% of children younger than 6 years and 50% to 60% of older children are anicteric.⁷ Thus most young children will not have signs or symptoms of hepatitis A, yet those who are infected may shed the virus for months. To identify hepatitis A infection in children who do not have symptoms, hepatitis A IgM antibody testing should be done.^{1,7,10} When acute infection is found in a child, secondary cases can be prevented by providing hepatitis A vaccine to unvaccinated family members and close contacts of the case.^{7,31,47} Although most children do not have symptoms, viral hepatitis should be considered in children with symptoms such as vomiting and loss of appetite, when accompanied by fever and an enlarged, tender liver even in the absence of jaundice.

Hepatitis B

Routine screening for hepatitis B virus (HBV) infection is recommended for all refugees and internationally adopted children.^{6,10,12,35,37} Most children who are hepatitis B carriers do not have symptoms. Therefore screening is important to identify these children so that appropriate management can be initiated and unvaccinated household contacts and caregivers can be vaccinated or be given hepatitis B immunoglobulin if they have had a significant exposure to blood of a hepatitis B carrier. The prevalence of hepatitis B infection is higher in resource-poor countries than in the United States. In Asia, Africa, and Central and South America, the prevalence of hepatitis B ranges from 2% to 7%, in contrast to only 0.5% in the United States.³⁴ Several studies have shown that rates of infection in refugee* and internationally adopted children mirror the reported rates in their country of origin. Immigrant children have typically acquired HBV by vertical transmission, although bloodborne infection and horizontal transmission also have been implicated. In international adoptees, the highest reported rates were in Romanian adoptees from the early 1990s, with 53% having evidence of past or present infection and 20% with active infection.^{60,71,73,100,104} Recent studies have consistently shown a lower range of prevalence (1–5%).^{4,15,57,66,87,89,90,93,94,106,119,131} Several reasons explain the high prevalence of hepatitis B infection in Romanian adoptees. During that period, Romania had an overall high prevalence of hepatitis B, and therefore many children in orphanages were infected with hepatitis B. Needles were commonly reused for immunizations and other injections. Transmission was facilitated through contaminated needles and close contact with children infected with hepatitis B. Hepatitis B vaccine was not used during that period. In addition, hepatitis B screening was not routinely done in children available for adoption; thus many children

arrived in the United States with unsuspected hepatitis B. In more recent years, hepatitis B vaccine in infants and screening for hepatitis B infection are routinely done and reported in the referral information. Thus the diagnosis of hepatitis B infection is nearly always known before adoption, and this condition is considered to be a special need.

Hepatitis B screening tests, including the hepatitis B surface antigen (HBsAg) and antibodies to surface (anti-HBs) and core (anti-HBc) antigens, are recommended in the medical evaluation of both internationally adopted children and refugees.^{6,10,12,35,37} All three tests should be done to determine whether the child is immune as a result of immunization (anti-HBs positive only), has recovered from infection (anti-HBs and anti-HBc positive), or has acute or chronic hepatitis B (HBsAg and anti-HBc positive).⁸ Patterns of hepatitis B serology can be found in Chapter 157. In a child found to be HBsAg positive, repeat testing should be done 6 months later. If the HBsAg persists for longer than 6 months, the child has chronic hepatitis B infection. If the child no longer has HBsAg and has developed anti-HBs, the child had acute infection and has recovered and is no longer able to transmit the virus to others. Children with acute or chronic hepatitis B (positive HBsAg) can transmit hepatitis B to others. A positive hepatitis B IgM differentiates acute hepatitis B from chronic hepatitis B. Children with acute or chronic hepatitis B should have additional testing done, including testing for HBeAg, HBeAb, and serum hepatic enzyme levels. HBsAg-positive children should be followed closely by a hepatologist for management.

Hepatitis D virus (HDV), which is seen only in patients with hepatitis B infection, occurs in North Africa, parts of South America, and the Mediterranean Basin.⁸ Testing for HDV is not widely available but is recommended in patients from these regions who are found to have hepatitis B infection; however, a positive test does not change clinical management. For children who initially test negative for HBsAg, HBsAb, and HBcAb, some experts recommend repeat testing for hepatitis B approximately 6 months after arrival to ensure the child was not infected just before arrival to the United States.¹⁰ Children with acute or chronic hepatitis B should have serologic testing for hepatitis A to determine the need for immunization with hepatitis A vaccine and for hepatitis C for overall management and treatment considerations.

Ideally, the family members of internationally adopted children should be vaccinated against hepatitis B before the child joins the family. If this has not been done, the household contacts of children with acute or chronic hepatitis B (HBsAg positive) must be vaccinated promptly. Hepatitis B is easily transmitted to unvaccinated household contacts. Up to 20% of household contacts will become HBsAg positive with 5 or more years of exposure within the home,^{43,60} and transmission of hepatitis B from newly adopted children to their parents has been documented.^{50,60,67,113}

Hepatitis C

Screening for hepatitis C is recommended for all internationally adopted children because most children with hepatitis C do not have symptoms, screening for risk factors is generally not possible, effective treatment and close follow-up of patients with hepatitis C are available, and there are high rates of hepatitis C in the countries of origin of adoptees.^{6,10} In refugees, testing is recommended based on a history of specific risk factors, such as current or former injection drug use, receipt of blood products, or residence in settings with a documented high prevalence of hepatitis C.^{6,10,37} Data on the prevalence of hepatitis C in both refugee^{53,54,91,92,102} and internationally adopted children^{57,70,104,106,110,131} are limited. In all families with internationally adopted children, the prevalence of hepatitis C was less than 1%.¹⁰⁶ In studies in refugees, the prevalence ranged from less than 2%^{53,54,91,92,102} to 7% in Thai Hmong refugees.⁹¹ Antibody testing with an enzyme immunoassay (EIA) should be done with the initial screening. If the antibody is positive, PCR should be done to confirm infection. Maternal antibody may be present until a child is 18 months of age. Children found to have hepatitis C infection should be immunized for hepatitis A and B and should be referred to a hepatologist for further management (see Chapter 177).

Human Immunodeficiency Virus 1 and 2 Infections

In the past, as part of the required overseas medical assessment, HIV testing was required for all immigrants and refugees 15 years of age

*References 12, 21, 22, 39, 45, 56, 62, 67, 85, 91, 92, 97, 99, 102, 127, 130.

†References 4, 10, 15, 57, 60, 64, 63, 65, 66, 71, 74, 75, 87, 89, 90, 93, 94, 106, 110, 119, 131.

and older. Children younger than 15 years of age were tested for HIV if history or examination raised concern about possible HIV infection (e.g., maternal history of HIV infection or history of rape or sexual assault). Since January 2010, HIV testing is no longer required for immigration medical assessment. The exception is that HIV testing still is recommended for people diagnosed with active TB. For refugees, HIV testing is recommended after arrival in the United States for persons age 13 to 64 years and encouraged for those younger than 13 years (<http://www.cdc.gov/immigrantrefugeehealth/guidelines/domestic/screening-hiv-infection-domestic.html>).³⁵

The decision to screen children younger than 13 years depends on history and risk factors (e.g., receipt of blood products and maternal drug use), physical examination findings, and prevalence of HIV infection in the child's country of origin. If there is a suspicion of HIV infection, testing should be performed before administration of live vaccines.³⁷

In contrast, most internationally adopted children have been tested for antibodies to HIV-1 by EIA in their birth country. In Ethiopia, an HIV-1 PCR test is generally also done. In children born to mothers with HIV and found to have antibodies to HIV in their country of origin, HIV-1 PCR testing is generally done. In more recent years, children known to be exposed to HIV have been given antiretroviral drugs when diagnosed in their birth country. For internationally adopted children, routine screening by EIA is recommended after they have arrived to the United States.^{6,10}

Reports of HIV infection in internationally adopted children were uncommon until recent years. In the early 1990s, two cases of Romanian adoptees with HIV infection were reported.⁷³ Subsequently, Romania was found to have high rates of HIV in institutionalized children that were not felt to be maternally transmitted.⁵⁹ The high prevalence was found to be associated with transmission through contaminated needles and blood products. In a more recent case series, there have been no reports of HIV infection in adoptees.¹⁰⁶ In contrast to past years when children infected with HIV were not permitted to be adopted internationally, these children may now be adopted by families in the United States. Many children with HIV infection have now joined their new families through adoption, and they have generally been treated with antiretrovirals before arrival.¹³⁹

For internationally adopted children, HIV testing with an enzyme-linked immunosorbent assay (ELISA) is recommended shortly after their arrival. Positive or indeterminate results should be resolved with use of HIV DNA PCR to detect HIV-1 virus (see Chapter 192B). If antibody testing by EIA is negative and clinical suspicion exists for HIV infection, HIV DNA PCR testing should be done. Some experts recommend PCR for any infant younger than 6 months on arrival. If PCR testing is done, two negative results from tests done 1 month or more apart with at least one done after 4 months of age are needed to exclude infection. Retesting children older than 6 months of age after arrival to the United States should be considered.⁵ Clinicians should be prepared to provide care and resources for children arriving to the United States with HIV infection.

Preadoptive testing for HIV-2 infection is not performed routinely. HIV-2 infection is prevalent in some African nations and is now recognized on several other continents; perinatal transmission appears to be limited. Symptoms suggestive of HIV infection with negative ELISA results for HIV-1 should prompt testing for HIV-2.⁵

Bacterial Infections

Syphilis

Refugees and internationally adopted children 15 years and older are routinely screened for syphilis before coming to the United States.^{6,9,37} Immigrants with positive results are required to complete treatment before arriving to the United States. On arrival to the United States, screening of all refugees 15 years and older is recommended regardless of the overseas results.^{6,35} Children who are younger than 15 years should be screened if there is a history of sexual activity or sexual assault or a history of maternal syphilis.^{6,37} In addition, all refugees emigrating from a country endemic for other treponemal infections such as yaws, bejel, or pinta should also be screened. Refugees of any age should be tested if there is clinical suspicion for syphilis.

Most internationally adopted children will have documentation of syphilis screening done in their birth country. For children with a history of syphilis or syphilis exposure, it is difficult to determine when the birth mother contracted syphilis and if she was treated and followed appropriately. In addition, in children with suspected syphilis exposure, details of the evaluation and prescribed treatment regimens are often incomplete or uninterpretable. Even though syphilis has rarely been reported in adoptees,^{4,15,57,63–66,71,87,89,90,94,106,110,131} all internationally adopted children should be screened on arrival with both a nontreponemal test (rapid plasma reagin, Venereal Disease Research Laboratory, automated reagin test) and a treponemal test (microhemagglutination–*Treponema pallidum*, fluorescent treponemal antibody absorption, or *T. pallidum* particle agglutination) (see Chapter 144).⁵ A positive treponemal test result warrants a complete and thorough evaluation to document the extent of the disease and to ensure adequate treatment regardless of a report of prior treatment. Because a positive treponemal test may be seen in pinta, bejel, yaws, and syphilis, it is important to consult with a specialist with expertise in these infections if the child is from a country where other treponemal infections are endemic.

Tuberculosis

TB is highly prevalent in the countries of origin for both refugees and internationally adopted children.^{6,9,35,37} Therefore screening on arrival to the United States is recommended for both groups.^{5,12,36,37} In the United States, 60% of all TB cases in the United States are among foreign-born people.⁹⁸ The rate of TB in foreign-born persons in the United States is 18.1 per 100,000; in US-born persons, the rate is 1.6 per 100,000. In addition, in the United States in 2009, the majority (89.4%) of multidrug-resistant TB cases were in foreign-born persons. In children, 22% of TB cases were in foreign-born patients. Case rates were significantly higher in foreign-born children (12.2 per 100,000) than in children born in the United States (1.1 per 100,000).^{33,96}

Both refugees and internationally adopted children are at increased risk for TB infection. In immigrants and refugees, a high prevalence of latent tuberculosis infection (LTBI) was found in studies conducted in Minnesota (49%),¹³⁴ San Francisco (40%),⁴⁴ Buffalo (20%),⁸⁵ and Maine (35%).⁵⁶ A study in San Diego County found that 7% of immigrants screened had active pulmonary TB and 76% had LTBI.⁸⁰

Overall, LTBI in internationally adopted children* appears to be lower (~20%) than that seen in refugees, which has been as high as 70% in certain populations.[†] This is likely due to the younger age and lower risk of living conditions of in this group of children. However, with the increased numbers of children coming from Ethiopia, a country with higher rates of tuberculosis, the rate of LTBI and tuberculosis in internationally adopted children is likely to increase. In two large studies in which all tuberculin skin tests (TSTs) were evaluated by a health care professional, 14% to 21% of international adoptees had LTBI.^{82,129} The highest proportion with LTBI was seen in children from Russia and Eastern Europe (29%), and the lowest was in children adopted from China (10%).¹²⁹ Of note, very few children from Africa were included in these studies. Children with initially negative TSTs had their TSTs repeated at least 3 months later, and 13% to 20% of the TSTs were positive, suggesting that a high proportion of children initially had false-positive TSTs. The authors postulate that this could be due to anergy, testing too soon after infection, or boosting from TB infection or bacille Calmette-Guérin (BCG).

TB disease in international adoptees has rarely been reported.^{42,57,75,76} In the first series of Korean adoptees, the overall prevalence was less than 1%, but two children had active TB and both had nonreactive TSTs.⁷⁵ One child had pneumonia caused by *Mycobacterium tuberculosis* and recovered. The other child had TB meningitis and died. These cases illustrate the importance of considering TB in the differential diagnosis even in children with negative TSTs. In the second case report,⁴² a child with TB adopted from the Marshall Islands infected his female guardian and 20% of the contacts identified. On arrival in the United States, he had a TST done, but the test was never read. He had cavitary TB, but

*References 4, 52, 57, 63–66, 71, 75, 81, 82, 87, 89, 90, 94, 101, 106, 115, 129, 131, 132.

†References 12, 21, 39, 44, 56, 79, 80, 85, 97, 99, 102, 105, 125.

it was not diagnosed until his guardian developed TB. In a 2016 study examining the health status of internationally adopted children from Ethiopia, 6 of 315 children (2%) were found to have active tuberculosis.¹³¹

In the past, refugees older than 15 years and children younger than 15 years with concern about TB exposure or disease were screened with a chest radiograph before arriving in the United States. If the chest radiograph was abnormal, microscopic evaluation of sputum or gastric aspirate for acid-fast bacilli is performed. Refugees who were sputum positive were banned from entry until sputum smears were negative. In 2007, a major revision of the overseas TB screening requirements for immigrants and refugees bound for the United States was implemented that required TB screening for all people.³⁵ International adoptees from certain countries with high rates of TB (China and Ethiopia) now fall under the same requirements as other immigrants and refugees. For other adoptees, screening in the country of origin appears to be inconsistently done and generally is documented only in older children.

For both refugees and internationally adopted children, screening for TB should be done shortly after arrival to the United States.^{6,9,12,35,37} Testing can be done at the initial assessment by placement of a TST (5 tuberculin units purified protein derivative) (Fig. 233.2). The test should be read 48 to 72 hours later by a health care professional. A reading of 10 mm or greater of induration is considered positive for both refugees and internationally adopted children arriving from a country endemic for TB. A reading of 5 mm or more is considered positive if there is a known contact with a person with active TB, an abnormal chest radiograph finding, signs or symptoms suggestive of TB, or evidence of immunosuppression. Children with a positive TST should have a thorough physical examination and chest radiograph performed to assess for *M. tuberculosis* disease. If the chest radiograph and physical examination are normal and the skin test is 10 mm or greater of induration, the diagnosis of LTBI is made and treatment with a 9-month course of isoniazid is begun. Similarly, a child with 5 to 9 mm of induration who has known exposure to someone with active TB or who is receiving immunosuppressive therapy or has an immunosuppressive condition, including HIV, with no evidence of disease, should receive isoniazid therapy as well. Retesting of TST-negative children 6 months or longer after arrival should be considered for all children given the high rate of false-negative TSTs shortly after arrival to the United States.^{9,82,129}

Interferon- γ release assays (IGRAs), such as QuantiFERON Gold and T-SPOT.TB, are acceptable alternatives to the TST but are not currently recommended for children younger than 5 years, because of the lack of published data for younger children.^{6,9} These assays use antigens that are secreted by *M. tuberculosis*-complex organisms but not by the Calmette-Guérin bacillus from the BCG vaccine. For TB disease, their sensitivity is comparable to that of the TST in children 5 years or older. For TB infection, the specificity of these tests is higher

than that of TSTs, but the sensitivity is not known. Logistical issues exist with the use of these tests because the test relies on stimulation of live blood mononuclear leukocytes with antigen, *in vitro*. In addition, these tests are more expensive than TSTs. For immunocompetent children 5 years and older, IGRAs can be used in place of a TST to confirm cases of TB or cases of LTBI. Similar to a positive TST, a child with a positive result from an IGRA should be considered infected with *M. tuberculosis* complex; however, a negative result from an IGRA cannot definitively rule out TB infection. IGRAs have the advantage of not requiring a follow-up visit for reading the TST or individual interpretation of the TST result. Studies done comparing TST with IGRAs in immigrant populations have found poor concordance with positive tests, with fewer positive results using the IGRA tests.^{115,125}

Although most refugees and internationally adopted children with *M. tuberculosis* infection have LTBI, disease should be considered in children with pneumonia or nonspecific symptoms such as fever, malaise, growth delay, weight loss, cough, night sweats, and chills. In children, pulmonary TB is the most common site of infection, accounting for 77% of cases, followed by lymphatic TB in 16% of children.⁹⁶ Chest radiographs may reveal adenopathy, segmental or lobar infiltrates, or pleural effusion. Cavitory lesions and miliary disease are less commonly seen. Extrapulmonary manifestations of the central nervous system, middle ear and mastoids, lymph nodes, bone, joints, and skin also can be seen. Every effort should be made to recover the organism in children with suspected disease to determine the susceptibilities of the organism. Many children arrive from countries in which drug-resistant *M. tuberculosis* is common. Gastric aspirates, bronchoscopy, or both can be useful adjuncts in a child too young or too ill to expectorate sputum.

Initial management of active TB disease in refugees or internationally adopted children should include isoniazid, rifampin, pyrazinamide, and at least one other agent to ensure bactericidal coverage while culture results and susceptibility testing are pending (see Chapter 96).¹¹ The most recent resistant patterns from the child's country of origin should be considered along with any other epidemiologic information that can be obtained when making treatment decisions, especially if the cultures are negative.

Vaccination with BCG is common in most resource-poor countries. A history or evidence of BCG vaccine receipt is not a contraindication to the placement of a TST.^{9,11} Studies have demonstrated that placement of a TST after BCG vaccination fails to elicit induration of 10 mm or greater.^{78,108} Thus the history of BCG vaccine should not affect the interpretation of purified protein derivative.

BCG vaccination can be recognized by a 2- to 4-mm scarification, often seen on the left deltoid. Documentation of vaccination should be made in the child's vaccine record, and the scar, if present, should be documented on the physical examination record. Occasionally, complications from BCG vaccination can occur. These may include enlargement of regional lymph nodes or a nodule or ulcer that may or may not be draining at the vaccination site (Fig. 233.3). The lesion is granulomatous; culture of the lesion will yield *Mycobacterium bovis*. No consensus exists regarding the management of this condition. The outcome of these lesions varies. Some lesions resolve without treatment. Other lesions have been excised for diagnostic reasons, and others have been reported to require excision. Medical treatment with isoniazid, erythromycin, or clarithromycin has been used with success.^{49,128}

Enteric Bacterial Infections

In contrast to intestinal parasites, bacterial enteric pathogens appear to be less common in immigrants and adoptees; however, most studies have not assessed systematically for bacterial causes. Children with bloody diarrhea or diarrhea associated with high fever should have stool examined for bacterial enteropathogens (e.g., *Salmonella*, *Shigella*, *Yersinia*, and *Campylobacter*) as part of the initial evaluation. Some experts also recommend obtaining stool cultures in newly arrived adoptees with diarrhea.⁵ However, if a bacterial pathogen is identified, treatment may not be indicated or needed if symptoms have resolved.

Intestinal Parasites

Intestinal parasites are common in both refugee^{14,18,21,77,79,92,102,105,107,122,127,137} and internationally adopted^{4,57,71,75,87,89,90,94,106,110,116,131} children (Table 233.2).

FIG. 233.3 Internationally adopted child from Vietnam with a bacille Calmette-Guérin granuloma on the shoulder.

TABLE 233.2 Pathogenic and Nonpathogenic Intestinal Parasites		
Parasite Type	Pathogens	Nonpathogens
Protozoa	<i>Giardia intestinalis</i>	<i>Endolimax nana</i>
	<i>Entamoeba histolytica</i>	<i>Entamoeba coli</i>
	<i>Dientamoeba fragilis</i> ^a	<i>Entamoeba gingivalis</i>
	<i>Balantidium coli</i>	<i>Entamoeba hartmanni</i>
	<i>Blastocystis hominis</i> ^a	<i>Entamoeba polecki</i>
	<i>Isospora belli</i>	<i>Iodamoeba bütschlii</i>
	<i>Cryptosporidium parvum</i>	<i>Chilomastix mesnili</i>
	<i>Cyclospora cayentensis</i>	<i>Enteromonas hominis</i>
	<i>Microsporidium</i> spp.	<i>Retortamonas intestinalis</i>
		<i>Trichomonas hominis</i>
		<i>Trichomonas tenax</i>
Helminths		
Nematodes	<i>Ascaris lumbricoides</i> (roundworm)	
	<i>Trichuris trichiura</i> (whipworm)	
	<i>Strongyloides stercoralis</i> (threadworm)	
	<i>Enterobius vermicularis</i> (pinworm)	
	<i>Necator americanus</i> (hookworm)	
	<i>Ancylostoma duodenale</i> (hookworm)	
Cestodes	<i>Hymenolepis</i> spp.	
	<i>Taenia saginata</i> (beef tapeworm)	
	<i>Taenia solium</i> (pork tapeworm)	
	<i>Schistosoma</i> spp.	

^aControversy exists regarding the pathogenicity of this organism.

Rates of infection vary by age and country of origin. Most children typically have not had testing before coming to the United States. However, presumptive treatment of refugees from certain regions before departure to the United States has been recommended since 1999, and screening strategies for these two groups are different.^{6,35,37,83,122} Presumptive treatment has been found to be cost-effective in refugee populations.^{69,83,122} Specifically, all refugees from the Middle East and South and Southeast Asia are recommended to receive a single dose of albendazole for round worms and ivermectin for *Strongyloides*. African refugees also should receive presumptive treatment for *Strongyloides*, and for those originating from areas endemic

for schistosomiasis, presumptive treatment with praziquantel should be given. In African countries where Loa Loa is endemic, ivermectin should not be given for *Strongyloides* because treatment with this drug in the presence of Loa Loa has been associated with encephalopathy. Therefore in Loa Loa–endemic areas, 7 days of albendazole should be given. Additional details of the country-specific recommendations, timing, dosing, and duration of treatment can be found in the Centers for Disease Control and Prevention (CDC) guidelines for refugee and immigrant care.^{35,37}

In internationally adopted children, the reported prevalence of intestinal parasites has varied from 9% to 51%, depending on the age of the child and country of origin.^{4,57,71,75,87,89,90,94,106,110,116,131} Older children and children originating from countries other than Korea have been found to be at highest risk for intestinal parasites. *Giardia intestinalis* has been the most commonly identified pathogen in all studies, with as many as 19% of children infected. Helminth infections have been less frequently identified (<3%), with *Hymenolepis* spp., *Ascaris lumbricoides*, and *Trichuris trichiura* most often reported. In the largest study, the overall prevalence of intestinal parasites in internationally adopted children was 29%.¹¹⁶ In this study, the prevalence of intestinal parasites was similar in children with and without gastrointestinal symptoms, and no significant difference was seen in malnourished children in contrast to children who were not malnourished.

Several studies report the prevalence of intestinal parasites in refugees, but few give pathogenic-specific data by age and country. In a large study of 26,956 refugees from Southeast Asia and Africa, the prevalence of intestinal parasites was examined.¹²² The median age was 19 years, and 30% were children 2 to 14 years of age. For African refugees who were not pretreated, 7% had *Giardia* and 24% had at least one nematode, with *Trichuris* being most commonly identified. For Southeast Asian refugees, 12% had *Giardia* and 19% had at least one nematode, but hookworms were the most prevalent, at 11%. Children 2 to 14 years of age were significantly more likely than adults to have *Ascaris*, *Trichuris*, and *Giardia*, whereas hookworms were found more often in adults. In contrast, in another study, 17% of refugee children were found to have *Giardia* and 19% had helminths, with hookworms most commonly seen.¹⁴ This study found a high rate of hookworm in Bosnian refugees and found different rates of overall and pathogenic-specific recovery by region. Interestingly, this study found that refugees who reported gastrointestinal symptoms were significantly less often infected than those without symptoms ($P < .001$). In a study conducted from 2013 to 2015 evaluating unaccompanied minor Syrian refugees, 7% were found to have *Giardia* and 1.4% were diagnosed with schistosomiasis.⁹²

Both refugees and adoptees should be screened for intestinal parasites on arrival to the United States.^{6,9,12,19,35,37} The diagnosis for most intestinal parasites is done by examination of stool preserved in formalin and polyvinyl alcohol or sodium-acetate formalin for ova and parasite testing. Testing multiple stool specimens increases the sensitivity of microscopic examination for ova and parasites.^{19,61,116} In one study in internationally adopted children, the sensitivity was 79% using one specimen and 92% for two specimens, and a third specimen identified parasites in an additional 8% of children.¹¹⁶ Examination by an experienced technologist is critical in identifying intestinal parasites. One stool specimen should also be evaluated for *G. intestinalis* and *Cryptosporidium parvum* using antigen testing.^{6,9} Repeat stool samples are essential to assess the effectiveness of treatment for the identified parasite or determine the presence of new (or newly found) pathogens. If the child remains persistently symptomatic, additional stool sample examinations are warranted, and testing for other parasites such as *Cyclospora* and *Strongyloides stercoralis* should be considered.

Eosinophilia and Tissue Parasites

In refugees or internationally adopted children who have negative stool ova and parasite examinations and in whom eosinophilia (absolute eosinophil count exceeding 450 cells/mm³) is found on complete blood count, additional serologic testing should be done.^{6,9,12,37,84,112} Children infected with these parasites often do not have symptoms.⁹⁵ In refugees, several studies have found eosinophilia to be very common, with a range of prevalence from 12% in asymptomatic refugees¹¹² to 9% to 28% in refugees with and without symptoms.^{20,95,97,99} In one study

conducted in international adoptees, 21% of children were found to have eosinophilia.⁵⁷ In both refugees and internationally adopted children, the most common cause of the eosinophilia was a helminth infection diagnosed by ova and parasite testing, or *Strongyloides*, schistosomiasis, or filariasis diagnosed by serology.

Serologic testing for *S. stercoralis* should be performed on all children with eosinophilia and no identified pathogen commonly associated with an increased eosinophil count, regardless of country of origin. Serologic testing for *Schistosoma* spp. should be performed in children with eosinophilia and no identified pathogen commonly associated with eosinophilia from sub-Saharan Africa, Southeast Asia, or areas of Latin America where schistosomiasis is endemic.

Testing for filariasis should be done for children older than 2 years with eosinophilia who come from areas where filariasis is endemic. Multiple parasites cause filariasis; therefore, if testing is positive, consultation with an infectious disease specialist with expertise in this disease should be done to ensure the correct treatment is given. Serologic testing for *Strongyloides*, *Schistosoma* spp., and filariasis is available through the CDC.

While eosinophilia should prompt clinicians for evaluation for helminths and tissue parasites, it is important to realize that these parasites may be present without eosinophilia.^{95,114} Some experts will perform serologic tests for all refugees and international adoptees regardless of the presence of eosinophilia if children immigrated from an area endemic for these parasites.

Chagas Disease (American Trypanosomiasis)

Chagas disease is endemic throughout much of Mexico, Central America, and South America (Chapter 221) and is caused by *Trypanosoma cruzi*.⁹ The risk for Chagas disease varies by region within countries with endemic infection. Although no studies have been done to assess the prevalence of Chagas disease in refugees or internationally adopted children, screening is warranted because treatment of infected children is highly effective in contrast to treatment in adults.^{5,26,37,38} Children may become infected by vertical exposure or from vectors. Countries with endemic Chagas disease include Argentina, Belize, Bolivia, Brazil, Chile, Colombia, Costa Rica, Ecuador, El Salvador, French Guiana, Guatemala, Guyana, Honduras, Mexico, Nicaragua, Panama, Paraguay, Peru, Suriname, Uruguay, and Venezuela. Serologic testing should only be performed in children 12 months of age or older because of the potential presence of maternal antibody. Testing can be done through the CDC.

Malaria

For internationally adopted children, routine screening for malaria is not recommended.⁴ In refugees who do not have a contraindication, predeparture presumptive antimalarial therapy with artesunate-combination therapy should be given to all sub-Saharan African refugees arriving from countries endemic for *Plasmodium falciparum*.^{35,37} Refugees from these countries without presumptive treatment before departure should have postarrival testing done using malaria PCR. If PCR is not available, traditional blood films or a rapid antigen test may be used, recognizing that these tests are much less sensitive, especially in persons who do not have symptoms. Alternatively, presumptive treatment can be provided instead of testing. Refugees from malaria-endemic regions outside sub-Saharan Africa do not require postarrival testing or treatment. However, any refugee or internationally adopted child from a malaria-endemic region with signs or symptoms of malaria should be thoroughly evaluated.

Routine screening for malaria is not recommended for internationally adopted or refugee children.^{6,9,37} Screening of symptom-free children from endemic areas may be indicated in children with splenomegaly. A study done in internationally adopted Ethiopian children from 2006 to 2011 found that 14% of children who had past or current hepatomegaly or splenomegaly and previously lived in a malaria-endemic area had asymptomatic parasitemia by microscopy or PCR.²

Multidrug-Resistant Organisms

Routine screening for carriage of multidrug-resistant organisms is not recommended in internationally adopted or refugee children. Several

studies, however, have demonstrated high rates of carriage and in some cases transmission of drug-resistant bacteria, including extended spectrum β -lactamase (ESBL)-producing organisms.^{13,15,16,51,55,57,58,124,126,133} A study of adoptees from Mali found that 24 of 25 children screened carried at least one ESBL-producing organism on arrival to France.¹²⁴ In another study of adoptees from Mali, ESBL was produced by 26 of 41 *Salmonella* species isolated from 30 families.¹⁶ A study conducted in pediatric refugees hospitalized in Germany from 2015 to 2016 found that 34% of the 325 children had multidrug-resistant organisms.¹²⁶ Additional information is needed to determine whether recommendations for screening should occur. For now, health care providers should be aware that immigrant children might have high rates of multidrug-resistant organisms.

Other Testing

A complete blood count is recommended for refugees and internationally adopted children.^{6,9,37} The hemoglobin and red blood cell indices may identify children with anemia, iron deficiency, hemoglobinopathies, or malaria. Low white blood cell counts and lymphopenia may indicate HIV infection or malnutrition. Eosinophilia is common among refugees and suggests parasitic infection. The prevalence of eosinophilia has not been reported in internationally adopted children. For refugees, a urinalysis is recommended to assess for hematuria and pyuria. Hematuria may indicate schistosomiasis, and pyuria may reflect a urinary tract infection or renal TB.

Elevated blood lead levels have been reported in internationally adopted children²³ and refugees,²⁹ and both groups should have a blood lead concentration as part of their initial evaluation.^{6,9,37}

OTHER VACCINE-PREVENTABLE DISEASES

In addition to hepatitis A and hepatitis B, other vaccine-preventable diseases have been transmitted or brought into the United States by immigrants. One case of pertussis in an internationally adopted child from Russia has been reported,²⁵ along with several cases of measles imported by refugees³² and internationally adopted children.^{24,26-28,30} Clinicians should be aware of the signs and symptoms of measles and do proper testing if measles is suspected.

Dermatologic Infections and Infestations

Lice, scabies, fungal infections, and molluscum contagiosum are common in both refugees and internationally adopted children. The prevalence of these conditions has not been well documented. In three studies conducted with international adoptees, 35% to 70% had dermatologic conditions, including tinea, scabies, staphylococcal infections, and molluscum.^{57,103,131} In refugee populations, the reported dermatologic conditions included these same conditions but were broader with leishmaniasis, tungiasis, and leprosy were also reported.^{39,41,72,97,121} The physical examination should include careful evaluation for these entities so that appropriate treatment is given.

IMMUNIZATION GUIDELINES

Making immunization recommendations can be challenging for clinicians providing care for immigrant children. Most refugees arrive in the United States without immunization records, and most international adoptees have some documentation of receipt of immunizations. Refugee and internationally adopted children have typically had the opportunity to have received BCG, diphtheria-tetanus-pertussis-containing vaccines, poliovirus vaccine, hepatitis B, and measles vaccines in their countries of origin. In internationally adopted children, there has been an increase in documentation of *Haemophilus influenzae* type b vaccine, especially for children from South Korea, Guatemala, India, and China. For measles vaccine, most children will have received and have documentation of a monovalent measles vaccine. Mumps and rubella vaccines, in combination with measles vaccine as MMR, have been documented for adoptees from South Korea and Guatemala or as monovalent vaccines in older children from Eastern Europe and Russia. Pneumococcal conjugate and varicella vaccines are not routinely given but have been documented in records for children from South Korea and Guatemala. Although

TABLE 233.3 Serologic Testing for Verifying Immunization or Past Infection

Age	Test	Protective Level
Children ≥5 Months		
Diphtheria antibody (IgG)	ELISA	>0.10 IU/mL
Tetanus antibody (IgG)	ELISA	>0.10 IU/mL
Poliovirus antibody (serotypes 1–3)	Neutralizing antibody	Detectable antibody
Hepatitis B surface antibody (IgG)	ELISA	≥10 mIU/mL
<i>Haemophilus influenza</i> type b, (IgG) polyribosylribitol phosphate antibody	ELISA	≥1.0 IU/mL
Children ≥12 Months		
Rubeola (measles) antibody (IgG)	IFA or ELISA	^a
Mumps antibody (IgG)	IFA or ELISA	^a
Rubella antibody (IgG)	ELISA	^a
Varicella antibody (IgG)	ELISA	^a
Hepatitis A antibody (Total or IgG)	EIA	^a

^aValue for positive result varies by test and laboratory.

children may have documentation of some vaccine-preventable diseases, a clinical diagnosis of measles, mumps, rubella, varicella, or hepatitis A from the child's country of origin should not be accepted as evidence of immunity.

The Immigration and Nationality Act (INA) of 1996 requires immigrant visa applicants to provide proof of vaccination with at least the first dose of vaccines recommended by the Advisory Committee on Immunization Practice (ACIP) before entry into the United States.^{3,6,9,37} These regulations apply to most immigrant children entering the United States; however, internationally adopted children who are 10 years or younger may obtain an exemption from these requirements. Adoptive parents are required to sign a waiver indicating their intention to comply with the ACIP immunization requirements within 30 days after the child's arrival in the United States. Refugees are not required to meet immunization requirements of the INA at the time of initial entry into the United States, but they must show proof of immunization when they apply for permanent residency—typically 1 year after arrival. Information about immunization requirements for immigrants is available on the CDC website (<http://www.cdc.gov/ncezid/dgmq/>).

People immunized in other countries, including refugees and internationally adopted children, should be immunized according to the US recommended schedule for healthy infants, children, and adolescents.^{3,6,9,37} Only written documentation should be accepted as evidence of previous immunization. The written records may be considered valid if the vaccines, dates of administration, numbers of doses, intervals between doses, and age of the patient at the time of immunization are comparable to current US or World Health Organization (WHO) schedules (http://apps.who.int/immunization_monitoring/en/globalsummary/countryprofileselect.cfm). Overall, most vaccines used around the world are produced with adequate quality-control standards and are generally considered reliable. Immunization is one of the most important measures used to prevent diseases in resource-poor countries, and immunization of children is a priority worldwide. However, some vaccines with inadequate potency have been produced in other countries. In addition, immunization records may be difficult to interpret or have dates that appear inaccurate, causing concern that the records may not be valid and accurately reflect protection. Therefore, for children who do not have a record or who have an unknown or uncertain immunization status, serologic testing and reimmunization are both reasonable approaches. If serologic testing is not or cannot be done, any immunizations that are not documented or do not adhere to the US or WHO standards should be repeated.

For children whose immunizations are not up to date, but who have a valid, written immunization record for the vaccines documented, vaccines as recommended for their age should be administered. For children without documentation of immunizations or who have a record that does not adhere to US or WHO standards, a new vaccine schedule may be initiated or measurement of antibody concentrations to any or all of the following vaccine antigens can be done: diphtheria, tetanus, poliovirus (each serotype), measles, mumps, rubella, varicella, and

hepatitis A (Table 233.3). Hepatitis B serology will be done to assess the child's hepatitis B status, which will also allow for determination of immunity. *H. influenzae* type b polyribosylribitol phosphate antibody also can be done; however, fewer data exist to support this testing to determine protection. Testing for measles, mumps, rubella, varicella, and hepatitis A should only be done in children older than 12 months because of the possible presence of maternal antibody. Because antibody testing for one vaccine may not be predictive for others, a combination of reimmunization and antibody testing also can be used. Serologic testing is not recommended for making vaccine decisions for pertussis, pneumococcus, or influenza. Because there are not reliable correlates of protection for pertussis, diphtheria and tetanus levels may be used to guide decision making. Age-appropriate immunization for conjugate pneumococcal and influenza vaccines is recommended.

Some caveats for interpreting antibody results should be reviewed. First, in general, antibody levels do not differentiate past disease from immunization. Measles, mumps, rubella, hepatitis A, varicella, and *H. influenzae* type b are prevalent in many of the countries of origin for refugees and internationally adopted children, so protective levels of antibody may be due to past immunization of infection. Poliovirus from oral poliovirus vaccine could be transmitted from another child, providing protection to children without documentation of poliovirus vaccine. For HBV, however, serology will distinguish between past disease and immunization. The presence of anti-HBc with anti-HBs reflects past, recovered disease, whereas anti-HBs alone is due to immunization. Second, if protective antibody is found, additional age-appropriate immunizations should still be given for some vaccines. For example, if a 9-month-old infant has protective antibody for diphtheria and tetanus, the 15- and 18-month and 4- to 6-year DTaP doses should still be given. In contrast, if a 3-year-old child has protective antibody to measles, mumps, and rubella, an additional MMR is not needed when the child is 4 to 6 years of age. Third, it is important to consider age, along with the antibody levels for diphtheria and tetanus. In a 3-year-old child with a protective level of 0.20 IU/mL for tetanus, a dose of DTaP should be given to boost the tetanus level and hopefully provide higher levels of protection for pertussis. Finally, if a child does not have protective antibody for measles, mumps, or varicella, two doses are needed. However, if measles and mumps antibody levels are protective and the rubella antibody is nonprotective, only one MMR dose is needed for rubella.

Several studies have been published examining antibody testing to verify the immunization status or immunity to vaccine-preventable diseases in internationally adopted children.* The results of these studies differ; some studies show inadequate protection, whereas others show good levels of protection. Differences in study design and laboratory methods likely account for the different results from the various studies. In the largest study to date, in internationally adopted children with three or more vaccine doses, overall protection was found to be high for diphtheria (85%), tetanus (95%), polio (93%), hepatitis B (77%),

*References 1, 40, 86, 87, 88–90, 94, 106, 109, 117–119, 132, 135, 136.

and *H. influenzae* type b (67%).¹¹⁷ Of children 12 months and older with more than one dose of measles, mumps, or rubella vaccine, 95%, 72%, and 94%, respectively, were immune. In contrast to children without documentation for a given vaccine antigen (i.e., no doses), a lower proportion of children had protective levels of antibody: diphtheria (69%), tetanus (76%), polio (83%), hepatitis B (42%), *H. influenzae* type b (67%), measles (58%), mumps (31%), or rubella (30%). However, many of these children were still protected, suggesting that children either had a history of disease or had received vaccines and did not have documentation. In that same study, 33% of adoptees had protective levels of varicella antibody (with or without vaccine documentation), and 83% of children with a history of varicella had protective antibody. Few data exist on verifying immunization status by antibody testing in refugees, with most focusing on measles, mumps, rubella, and varicella, and protective antibody increased with age and varied by country.^{46,68,105}

CONCLUSION

Providing care for refugees and internationally adopted children can be rewarding. Screening for infectious diseases and determining immunization needs is critical not only for the health and prevention of disease in these immigrants but also for the prevention of disease in their families and communities.

Soil bacteria developed mechanisms of resistance to antibiotics millions of years ago as a means of protecting themselves against other antibiotic-producing microorganisms or their own antimicrobial products. The current crisis of antibiotic resistance was prompted by the intense selective pressure posed by the worldwide use of antibiotics during the past 70 years. The problem of antimicrobial resistance in humans has been exacerbated by the widespread administration of antibiotics to farm animals.^{290,445,510} Resistant zoonotic bacteria selected by this practice contaminate the food supply and thereby spread to human consumers.

To understand antibiotic resistance fully, a distinction must be made between the *in vitro* phenomenon of resistance and the less frequently observed clinical consequences of the *in vitro* phenomenon. Much of the discussion of bacterial resistance to antibiotics derives from the apparent changes in susceptibility of pathogenic bacteria to the concentrations of antibiotic achieved in blood after standard antibiotic dosing. These concentrations have been established as breakpoints based on integration of data derived from clinical and animal studies along with the measurement of plasma and serum drug concentrations associated with successful outcomes. Unfortunately, such breakpoints are not absolute. Rather, they depend on an intricate interrelationship between the pharmacokinetics and pharmacodynamics of the drug.⁷⁴ As such, if one component of this complex association is changed, the apparent breakpoint distinguishing susceptibility from resistance possibly and mostly likely will also change. Consequently, in presenting information concerning the mechanisms of antibiotic resistance and their clinical contexts, one must remember that the discussion derives in part from certain artificial pretexts. Changes in a drug-dosing paradigm (e.g., dose, infusion duration, formulation) can affect the clinical relevance of the *in vitro* observations dramatically.

RESISTANCE GENETICS

Bacteria develop resistance to antimicrobial agents through three principal cellular mechanisms (Box 234.1). Two or more mechanisms of resistance to a given agent can exist simultaneously in the same microorganism.

Antibiotic resistance is spreading at an alarming rate across international boundaries. In some instances, antibiotic resistance spreads when a resistance-conferring mutation occurs in the bacterial chromosome and the mutated organism then disseminates throughout the community and beyond. Perhaps even more importantly, antibiotic resistance is spread through the acquisition of exogenous DNA encoding the resistance determinant. These nucleic acid elements can mobilize; that is, move from one genetic location within the bacterium to another or from one organism to another (i.e., conjugation) (see Box 234.1). Mobilization frequently results in a reduction in the fitness of the host organism,^{202,377} primarily through increased energy expenditure or from the insertion and disruption of other genes important to the bacterium's health. Consequently, mobilization typically is tightly controlled and is a relatively uncommon event,⁴⁷² occurring mostly when the environment surrounding the bacterium, particularly antibiotic exposure, clearly confers a survival benefit. Conversely, insertion and disruption of important bacterial genes may occasionally improve the organism's chance for survival. Disruption of DNA repair enzymes, for example, may render the bacterium hypermutable and thus better able to rapidly adapt to hostile surroundings through random mutation events.⁴⁷²

The genetic elements important in mobile antibiotic resistance, from largest to smallest, are termed plasmids, transposons/integrative and conjugative elements, integrons, and insertion sequences.

Plasmids

The largest of the mobilization antibiotic-resistance elements and the first to be appreciated historically are called *plasmids*. Plasmids are extrachromosomal segments of double-stranded DNA and are unique among the antibiotic resistance elements in being able to replicate independent of the bacterial chromosome. The smallest plasmids are less than 1000 bp and contain only the machinery to replicate. Larger plasmids additionally contain the genes for conjugation plus numerous accessory genes. These latter genes are inserted into the plasmid and express resistance to antibiotics and other bacteriocides and virulence factors, but they are unrelated to the replication and conjugative functions of the plasmid. The largest plasmids contain more than 500 accessory genes and approach the size of the bacterial chromosome. A given bacterial isolate can harbor many different plasmids simultaneously. Groups of plasmids containing homologous replicative sequences, however, usually are unable to be maintained in the same bacterial cell. This property has enabled them to be categorized as incompatibility groups, which are designated by lettered or numbered names with the prefix *Inc*. With the definition of many plasmids at the sequence level, some authorities have proposed categorizing them by more precise characteristics such as homology of critical plasmid genes.⁴⁴⁰

Plasmids are transmitted from microorganism to microorganism vertically during bacterial division and horizontally through conjugation. Conjugation of plasmids occurs through binding of the plasmid-encoded relaxase to a sequence called the *origin of transfer* (*oriT*). The relaxase carries a single strand of the plasmid to the plasmid-encoded type IV secretion system on the inner surface of the bacterial cell wall. The strand then is transferred to the recipient cell through an ATPase-dependent process, after which the complementary strand is synthesized and the element recircularizes as a double-stranded structure in the new host.⁴⁴⁰

Transposons and Integrative and Conjugative Elements

Transposons are mobile segments of nucleic acid that can transfer from one location to another, such as from different sites on the bacterial chromosome or from a chromosome to a plasmid.^{422,426} Transposons do not replicate independently and therefore must be integrated into the chromosome or a plasmid to propagate. Like plasmids, transposons include accessory genes that express antibiotic resistance and other products beneficial to the survival of the host. Movement of transposons is catalyzed by a transposon-encoded integrase^{417,427} located upstream from the accessory genes, which excises the segment from the surrounding nucleic acid. The transposon then forms a circularized intermediate before being integrated at an *attachment* (*att*) site in a different nucleic acid location through the action of the integrase.^{417,427}

Some transposons also carry genes that enable them to conjugate. They are included under the broad rubric of mobile genes called *integrative and conjugative elements* (ICEs). In silico analysis of ever-enlarging databases of bacterial whole-genome sequences has revealed that ICEs are very widespread and enormously varied. Although most previously described conjugative transposons exhibited low specificity regarding their insertion site, many ICEs characteristically display a strong preference for insertion into specific conserved loci on the host chromosome, such as the tRNA or the peptide release factor gene.^{202,377,472,516} ICEs vary in size between 100 and 500 kb.^{202,377} Their accessory genes are preferentially inserted into hot spots within the ICE, which allows integration of new genetic material such as new antibiotic resistance genes with minimal disruption of ICE or host chromosomal function.³⁷⁷

BOX 234.1 Cellular Mechanisms of Antibiotic Resistance and Their Transfer

Mechanisms

- Genes that encode enzymes that modify or degrade antibiotics
- Genes that modify the molecular targets for antibiotics
- Genes that code for changes in cell wall channels or active pumping mechanisms

Transfer

- Plasmids: extrachromosomal genetic elements made of circular double-stranded DNA <10 to >400 kb pairs; autonomous and self-reproducing; may be conjugative or nonconjugative
- Transposon/integrative and conjugative elements: mobile genetic elements in the bacterial chromosome or plasmid that confer a recognizable phenotype characteristic; incapable of self-replication
- Integrons: DNA sequences on bacterial chromosome or plasmid often linked to a resistance gene, which facilitate recombination among nonhomologous DNA sequences
- Insertion sequences: small mobile elements that carry no antibiotic resistance genes themselves but may facilitate the activation or mobilization of nearby resistance determinants

ICEs usually do not excise and conjugate unless exposed to some stimulating factor, such as induction of the bacterial SOS stress response to chromosomal DNA damage or through quorum sensing interactions of surrounding bacteria. When conjugation does occur, the mechanism of intercellular transfer in many ICEs is similar to that identified in plasmids—a single strand is bound to an ICE-encoded relaxase attached to an *oriT* sequence, and the complex engages a type IV secretion system for transfer to the recipient cell.^{202,516} Some ICEs employ other conjugative machinery, and in some instances, the mechanism of cell-to-cell transfer is unknown.⁵¹⁶

The organization of ICEs is similar to antibiotic resistance *genetic islands* on the bacterial chromosome found in organisms such as *Acinetobacter* spp., *Salmonella* spp., and *Pseudomonas* spp. Genetic islands are composed of complexes of resistance genes congregated on a single portion of the bacterial chromosome.^{377,472} Similar to ICEs, new resistance genes can be inserted into genomic islands with little disruption of chromosomal function.⁴⁷² Genomic islands are distinct from ICEs in that they do not include the genetic modules enabling them to conjugate independently. However, many genomic islands include cryptic ICE-like *oriT* sequences that can be recognized by the conjugative machinery of coresident ICEs, which then can promote horizontal transfer of the islands in *trans*. Indeed, genomic islands may be remnants of ICEs that have lost their conjugative functions.

Integrons

The accessory genes on plasmids and transposons are encoded by elements called *integrations*. Integrations are composed of segments of DNA that can capture and excise gene cassettes coding antibiotic-resistance genes. To disseminate, the integron first must insert into a plasmid or transposon.^{121,370,392} Integrations contain an integrase that catalyzes the incorporation and excision of the cassette into the integron and a promoter that mediates the expression of the resistance determinant; both are situated 5' to the cassette. The cassettes are small segments that usually encode a single antibiotic-resistance determinant. Hundreds of antibiotic-resistance cassettes have been characterized.^{86,121,370,392} At the 3' end of each cassette is a variable region called the *cassette attachment (attC) site*, which contains the sequences recognized by the integrase for incorporation of the gene cassette into the integron.^{286,392}

Several classes of integrons have been defined based on the sequence of the integrase and their preference for certain transposons. Most antibiotic-resistance integrons belong to class 1.^{86,286,392} A single integron may contain multiple antibiotic-resistance cassettes in tandem, all of which are controlled by the single integron promoter. However,

transcription of tandem cassettes can terminate prematurely, such that the cassettes closest to the integron promoter are transcribed at the highest level.^{370,392}

Insertion Sequences

The smallest elements involved in antibiotic resistance are called *insertion sequences* (ISs).²⁷¹ ISs are found in a broad variety of bacterial species. They are less than 2.5 kb and are composed exclusively of an integrase, the enzyme responsible for their insertion into other genetic material, plus terminal inverted repeats on either end. ISs usually are designated numerically (e.g., IS1, IS2).

ISs do not replicate or conjugate independently and do not contain accessory genes, but they can influence antibiotic resistance expression or mobilization in several indirect ways. For example, their insertion can disrupt a regulatory gene that normally suppresses the transcription of an antibiotic resistance determinant.^{271,472} In other circumstances, the IS integrase reads through its right-sided terminal sequence and then continues through downstream genes, which sometimes encode antibiotic resistance, before encountering a surrogate termination sequence; excision of the IS mobilizes the accessory gene.^{271,472} In addition, two ISs can insert on either side of an antibiotic-resistance gene, resulting in mobilization of the intervening sequence. These structures are called *composite transposons*, although they are structurally distinct from conventional unit transposons.^{271,472}

Summary

The importance of mobile resistance genes in promoting the explosive spread of antibiotic resistance cannot be overstated. If each bacterial cell had to develop antibiotic resistance mechanisms independently, the process would be dauntingly inefficient because the likelihood of a particular strain undergoing even two advantageous mutations spontaneously is extremely remote. However, the clustering of antibiotic resistance genes on mobile elements has given bacteria a profound survival advantage in the age of antibiotics by enabling the instant acquisition of multiple, ready-made resistance determinants. In this way, bacteria can become resistant to a host of antibiotics almost immediately after exposure and can efficiently transmit the resistance phenotypes to bacteria coresiding in the same host and to bacteria colonizing or infecting multiple hosts in the same community.

RESISTANCE TO SPECIFIC ANTIBIOTICS

The language of antibiotic resistance includes an ever-increasing array of abbreviations denoting specific resistance determinants. A glossary of the abbreviations of those determinants is provided in [Table 234.1](#).

β-Lactam Antibiotics

The β-lactam antibiotics are a diverse, highly effective family of drugs with broad activity against a wide variety of hospital- and community-acquired pathogens. The β-lactams are composed of four subgroups: penicillins, cephalosporins, monobactams, and carbapenems. Resistance to the β-lactams is mediated by one of two principal mechanisms: production of enzymes capable of hydrolyzing the β-lactam ring and alteration of the target bacterial molecules, the penicillin-binding proteins (PBPs).

β-Lactamase Production

Clinical relevance. The explosive development in antimicrobial therapeutics since the mid-20th century has been driven to a great extent by the impact of β-lactamases in the clinical setting. Shortly after penicillin became incorporated into the clinical armamentarium for the treatment of systemic infections, clinical failures were reported in patients treated for infections caused by *Staphylococcus aureus*. On further analysis, the failures were attributed to penicillinase, an enzyme elaborated and excreted by the bacteria that inactivated the antibiotic before it could produce its clinical effect. This finding led to the development of numerous new antistaphylococcal penicillins (i.e., isoxazolyl penicillins) that were not substrates for the enzyme.

At the same time, a newer class of β-lactam agents, the cephalosporins, was developed. A criterion for moving candidate drugs from this class to the clinic was resistance to inactivation by the penicillinase elaborated

TABLE 234.1 Glossary of Resistance Determinant Abbreviations

Resistance Determinant ^a	Resistance Phenotype
SHV, TEM	Early generation β -lactams
AmpC,* CMY	All β -lactams except cefepime and carbapenems
ESBL ^b	All β -lactams except carbapenems
KPC, OXA	All β -lactams
VIM, NDM, IMP	All β -lactams
<i>mecA</i>	Methicillin resistance in <i>S. aureus</i>
<i>erm</i>	Macrolides (MLS _B phenotype)
<i>mef</i>	Macrolides (M phenotype)
<i>dhps</i> , <i>dhfr</i> ^c	Trimethoprim-sulfamethoxazole
AAC, ANP, APH	Aminoglycosides
<i>rmt</i>	Aminoglycosides
<i>van</i>	Glycopeptides
<i>cfr</i>	Linezolid
<i>optrA</i>	Linezolid
<i>mprF</i>	Daptomycin
<i>gyrA</i> ,* <i>parC</i> * mutations	Fluoroquinolones
<i>micF</i>	Fluoroquinolones
<i>Qnr</i>	Fluoroquinolones
<i>acc(6')-Ib-cr</i>	Aminoglycosides and fluoroquinolones
<i>OqxAB</i> , <i>QepA</i>	Fluoroquinolones
<i>PmrA</i> / <i>PmrB</i> ,* <i>PhoP</i> / <i>PhoQ</i> mutations*	Colistin
<i>mgrB</i> *	Colistin
<i>mcr-1</i>	Colistin
CAT	Chloramphenicol

^aDeterminants in italics indicate genes; those not italicized indicate proteins. Determinants marked with an asterisk are encoded primarily on the bacterial chromosome; all others are encoded primarily on mobile elements.

^bIncludes late-generation SHV and TEM, CTX-M, and others.

^cTransmissible mutations of *dhps* conferring sulfonamide resistance in Enterobacteriaceae are designated *sul1*, *sul2*, and *sul3*.

by staphylococci. Further development of penicillins, cephalosporins, monobactams, and carbapenems was influenced significantly by the recognition that the penicillinase elaborated by staphylococci was representative of a larger class of enzymes that also existed in gram-negative organisms.

As gram-negative organisms such as *Escherichia coli* emerged as important clinical pathogens, their emerging resistance to aminopenicillins on the basis of β -lactamase elaboration spawned the development of a group of enzyme inhibitors, including clavulanic acid,³⁹¹ sulbactam, and tazobactam,⁸ each of which was structurally a β -lactam that could bind to and inactivate many β -lactamases. As it became necessary to expand the spectrum of the penicillins and cephalosporins to include some of the more itinerant gram-negative organisms (e.g., *Serratia* spp., *Enterobacter* spp., *Pseudomonas* spp.), β -lactamase stability emerged as a necessary attribute for clinical success. This expansion was accomplished through the addition of one of the β -lactamase inhibitors to members of the carboxy and acylureido class of penicillins or through structural engineering, such as that seen in the development of the second- and third-generation cephalosporins and carbapenems.

The inexorable challenges to antimicrobial susceptibility posed by the increasing number and specificity of β -lactamases has driven medicinal chemists to seek newer β -lactamase inhibitors that in combination with effective β -lactam antibiotics preserve their effectiveness in the face of bacterial adaptation.^{46,345} The first group of these non- β -lactam β -lactamase inhibitors, the diazabicyclooctananes (DBOs), were synthesized to expand the range of activity of the β -lactamase inhibitors beyond the serine-based, Bush-Jacoby group 2/Ambler class A β -lactamases that were inhibited by clavulanic acid, sulbactam, and tazobactam. The first to reach clinical practice was the tight-binding

reversible inhibitor avibactam.¹⁰⁷ This molecule also inhibited serine-based Amp C and carbapenem-hydrolyzing β -lactamases^{70,112} (classifications of β -lactamases are described later), none of which were suppressed by the prior inhibitors. This finding was followed by the development of other DBO inhibitors, which are in clinical trials.³⁴⁵ Simultaneously, a second group of non- β -lactam β -lactamase inhibitors was synthesized, leveraging the known effectiveness of boronic acids against a broad range of serine-based β -lactamases.¹⁶⁰

Three sentinel clinical events were most responsible for establishing β -lactamase as a prominent clinical problem in pediatric practice. In 1974, the first case of bacterial meningitis caused by ampicillin-resistant *Haemophilus influenzae* type b was reported.³¹⁹ This report resulted in marked changes in clinical practice. First, all infants and children with suspected bacterial meningitis were treated empirically with ampicillin and chloramphenicol (i.e., a drug not susceptible to degradation by bacterial β -lactamase) instead of with ampicillin alone. In addition, several newer antibiotics, particularly the second- and third-generation cephalosporins, were evaluated for their efficacy in this clinical setting. From these studies, ceftriaxone or cefotaxime emerged as the drug of choice for the empiric treatment of suspected or proven bacterial meningitis in children. This selection was based on greater potency against *H. influenzae* type b and β -lactamase stability.

The second circumstance resulting in the affirmation of β -lactamase as an important clinical problem in pediatrics was the recognition of *Moraxella catarrhalis*, a β -lactamase-producing organism, as the third leading cause of acute otitis media in infants and children and the emergence of amoxicillin resistance among the nontypeable strains of *H. influenzae*. β -Lactamase production in *H. influenzae* was thought to be particularly associated with therapeutic failure, spawning the development of oral second- and third-generation cephalosporins and newer macrolides as therapeutic alternatives for treating childhood otitis media.

By the early 1980s, β -lactamase-producing bacteria garnered additional attention from pediatricians because of their role as nosocomial pathogens. These bacteria became prominent as children with severe but survivable conditions (e.g., hematologic malignancies, solid organ transplantation) required immunosuppressive therapy and prolonged hospitalization, both of which predisposed children to hospital-acquired infections. With each succeeding decade, the number and variety of β -lactamase-producing, hospital-acquired bacteria increased. By the early 21st century, virtually all nosocomial *S. aureus*, coagulase-negative staphylococci, and enteric and nonenteric gram-negative pathogens elaborated β -lactamase. These organisms commonly encode multiple, distinct β -lactamases and express them simultaneously. Consequently, many bacterial infections currently acquired in the hospital are resistant to all β -lactam agents except for the higher-generation β -lactam- β -lactamase inhibitor combinations, the advanced-generation cephalosporins, or the carbapenems.

Mechanisms of resistance. The β -lactamases constitute a broad array of enzymes that hydrolyze the β -lactam ring of selected antibiotics (Fig. 234.1). Most β -lactamases are structurally similar to the PBPs, and the consensus is that at least some of the β -lactamases were derived evolutionarily from them.²⁹⁵ β -Lactamases can be identified in gram-positive and gram-negative bacteria. In gram-positive bacteria, the enzyme is secreted into the cell-free environment, whereas in gram-negative organisms, most of the enzyme is confined and concentrated in the periplasmic space between the cell wall and the outer membrane.

More than 2000 β -lactamases have been cataloged,^{47,45,194} and doubtless many more exist in nature. The β -lactamases have been categorized according to substrate preference, isoelectric focus, whether they are encoded on the bacterial chromosome or an episome, their ability to be inhibited by clavulanate, and their molecular structure. The molecular classification proposed in the 1980s by Ambler⁵ is still widely employed. Based on conserved and distinguishing amino acid motifs, this classification divides the β -lactamases into four classes: A through D. Ambler classes A, C, and D are categorized as serine β -lactamases; their three-dimensional structures are similar, and they all possess a serine-based catalytic site.³⁴⁸ Ambler class B enzymes, which require a metal cofactor, do not.

The classification system of Bush, Jacoby, and Medeiros, proposed in 1995⁴⁸ and updated by Bush and Jacoby in 2010,⁴⁷ divides these enzymes into three groups (with subcategories) and principally uses

TABLE 234.2 Properties of the Major Groups of β-Lactamases

Properties	Bush-Jacoby Group		
	1	2	3
Ambler class	C	A, D	B
Substrate preference	All but carbapenems	Varies ^a	Varies (carbapenems)
Chromosomal/plasmid	C/P	P	C/P
Distribution	Gram negative	Gram negative or positive	Gram negative or positive
Clavulanate inhibition	No	Yes	No
Inducible ^b	Yes	No	No

^aCan be divided into subgroups, including penicillinases, cephalosporinases, cloxacillinases, and carbapenemases. Enzymes frequently hydrolyze more than one group of β-lactam.
^bIndicates that normally repressed β-lactamase production can be induced by β-lactam exposure.
Data from Bush K, Jacoby GA, Medeiros AA. A functional classification scheme for β-lactamases and its correlation with molecular structure. *Antimicrob Agents Chemother.* 1995;39:1211–33.

FIG. 234.1 Mode of action of β-lactamases of Ambler classes A, C, and D.

substrate and inhibitor profiles to classify enzymes in a manner that correlates with their expressed phenotype in clinical isolates. The properties of these groups are described here and outlined in Table 234.2.

Bush-Jacoby group 1 (Ambler class C) AmpC β-lactamases. The group 1 enzymes (i.e., AmpC β-lactamases) hydrolyze virtually all β-lactam antibiotics, although to various degrees. The preferred substrates of AmpC β-lactamases are cephalosporins (including oxyiminocephalosporins), but the enzymes also hydrolyze benzylpenicillins, cephamycins, and monobactams. Hydrolysis rates are low against the fourth-generation cephalosporins (i.e., cefepime and cefpirome) and carbapenems due to low enzyme affinity, and these antibiotics remain therapeutic options.

The AmpC β-lactamases are resistant to inhibition by clavulanate. These enzymes typically are chromosomally encoded on a sequence labeled *ampC* present in a wide range of gram-negative bacteria; however, the AmpC β-lactamases are expressed in quantities sufficient to produce clinically important resistance only in selected species, including *Enterobacter cloacae*, *Serratia marcescens*, *Citrobacter freundii*, *Pseudomonas aeruginosa*, *Acinetobacter baumannii*, and *Morganella morganii*. In the absence of drug exposure, expression of the group 1 AmpC β-lactamases in these species is repressed by an upstream sequence labeled *ampR*

FIG. 234.2 Model for peptidoglycan recycling and β-lactamase induction in enterobacteria. The lytic transglycosylases in the periplasm cleave the bond between *N*-acetylglucosamine (GlcNac) and *N*-acetylmuramic acid (MurNAc) and form the peptidoglycan degradation product, *N*-acetylglucosaminyl-1,6-anhydro-*N*-acetylmuramyl-L-alanyl-D-glutamyl-meso-diaminopimelic acid (T). The AmpG permease transports T into the cytoplasm. The AmpD amidase recognizes specifically substrate containing anhydromuramic acid and cleaves the bond between it and L-alanine, releasing the stem tripeptide, L-Ala-D-Glu-m-A₂pm (I). Unprocessed T activates the AmpR transcriptional regulator, inducing β-lactamase production. Conversely, the tripeptide (I) recycles to form new peptidoglycan. By regulating the relative amounts of T and I, AmpD can control peptidoglycan composition. The regulatory function of the AmpC β-lactamase, if any, is unknown. (From Medeiros AA. Evolution and dissemination of beta-lactamases accelerated by generations of beta-lactam antibiotics. *Clin Infect Dis.* 1997;24[suppl 1]:S19-S45.)

(Fig. 234.2).^{295,361} Exposure of the bacteria to a β-lactam leads to the production and intracellular incorporation of a bacterial cell wall metabolite that is processed by the enzyme AmpD.^{190,257} In sufficient quantity, the AmpD substrate interacts with *ampR*, reversing the repression, and relevant quantities of the AmpC β-lactamase are thereby synthesized.

β-Lactam antibiotics induce AmpC β-lactamases by this mechanism to different degrees. Ampicillin, cefoxitin, and imipenem are potent inducers, whereas most of the third-generation cephalosporins are weak. However, spontaneous mutations leading to a dysfunctional AmpD enzyme that occur at high frequency in nature result in permanent de-repression of the *ampC* gene, which results in constitutive production of large quantities of the AmpC β-lactamase (see Fig. 234.2). De-repressed organisms are rendered highly resistant after this single mutational step. The third-generation cephalosporins are particularly prone to selecting AmpD mutants, and the clinical emergence of resistant de-repressed isolates during the course of treatment with a third-generation cephalosporin has been documented.^{67,218,466}

In organisms lacking or poorly expressing chromosomal AmpC β -lactamase genes, such as *E. coli*, *K. pneumoniae*, and *Proteus mirabilis*, genes mediating AmpC β -lactamase resistance can be acquired by transmissible plasmids that often harbor other antibiotic-resistance determinants. The CMY-2 gene, which is genetically related to the AmpC β -lactamases of *C. freundii*, encodes the most common plasmid-based AmpC (pAmpC) β -lactamase recovered from isolates of human and animal origin. However, several other pAmpC genes are circulating worldwide in gram-negative bacteria, including those encoding FOX, ACT, MIR, DHA, ACC, CFE, and LAT enzymes, all of which have unique origins.^{193,260}

Bush-Jacoby group 2 (Ambler class A and D) β -lactamases. The group 2 β -lactamases represent the largest and fastest-growing group of β -lactamases, largely due to the proliferation of newer enzymes with broad substrate specificities (see Table 234.2).^{45,47} The group 2 β -lactamases are encoded primarily on mobile genetic elements such as plasmids and transposons.^{162,229,349} These elements commonly contain resistance determinants to other antibiotic classes.

The plasmids are stable and frequently are maintained within the bacteria even in the absence of antibiotic pressure. Moreover, they can be transmitted by conjugation from organism to organism and across species, sometimes leading to a plasmid outbreak in a confined environment, such as a nursing home or intensive care unit (ICU), that is caused by different species containing the same plasmid. Alternatively, spread can be facilitated by circulating clonal strains of gram-negative bacteria containing the responsible elements. The group 2 enzymes have substrate preferences that have become increasingly broad with the introduction of each new class of β -lactam antibiotic and can be categorized as early group 2 β -lactamases, extended-spectrum group 2 β -lactamases, and group 2 carbapenemases.

Early group 2 β -lactamases. The prototypical early group 2 Ambler class A β -lactamases are included in the TEM and SHV families of enzymes, although large numbers of early enzymes not belonging to either of these families have been characterized. TEM-1, first identified in Europe in 1963, hydrolyzed ampicillin. During the ensuing decades, the TEM sequence mutated in a stepwise fashion (with each new iteration labeled sequentially: TEM-2, TEM-3, and so on), resulting in the ability of each new enzyme to degrade an ever-increasing number of β -lactam antibiotics.^{105,192,295} Many of these mutations widen a critical cavity, formed by the three-dimensional configuration of the molecule, containing the serine-active site at its bottom that is key to hydrolysis of the β -lactam ring.¹⁹⁴

Extended-spectrum β -lactamases. Of great importance among the group 2 Ambler class A enzymes are the extended-spectrum β -lactamases (ESBLs). ESBL-producing organisms are distributed worldwide, but their incidence varies geographically.³⁶⁰ Initially, bacteria elaborating ESBLs infected primarily critically ill, hospitalized patients,³⁵⁰ but these enzymes are being reported in increasing numbers in the community.^{304,368}

ESBLs confer a common resistance phenotype, namely, reduced susceptibility to benzylpenicillins, cephalosporins (i.e., first through fourth generation, including oxyiminocephalosporins), and monobactams, but to varying degrees. Susceptibility to the cephamycins and carbapenems is preserved.³⁵⁰ Common to other group 2 β -lactamases, hydrolytic activity typically is suppressed by the β -lactamase inhibitors.

The first ESBLs were molecular descendants of TEM-1 and SHV-1 and were found in *E. coli*, *K. pneumoniae*, and to a lesser extent, in *P. mirabilis*.¹⁶² Other families of ESBLs have been described.³⁶⁸ Concomitant with their molecular evolution, ESBLs have been identified in an ever-widening range of bacteria, including *Pseudomonas spp.*, *Acinetobacter spp.*, and multiple species of Enterobacteriaceae.³⁴⁹

Among the more important ESBLs are the heterogenous CTX-M family of enzymes, which are particularly active against cefotaxime and are responsible for the current pandemic of ESBL-producing *E. coli* infections.⁵⁵ The main contributor to this worldwide dissemination of ESBLs is the multidrug-resistant clone, multilocus sequence type (ST) 131 *E. coli* harboring the CTX-M-15 type ESBL.¹⁴ ST131 *E. coli* are a lineage of extraintestinal pathogenic *E. coli* (ExPEC) and are responsible for a significant proportion of urinary tract and

invasive infections worldwide. There are three major ST131 clades (i.e., A through C), which have different mobile genetic elements and recombinations of associated regions. The ST131 clade C strains make up the largest proportion circulating globally, and these strains possess several virulence determinants (i.e., ExPEC-associated genes), including the type 1 fimbriae FimH30 allele, and additional antibiotic resistance determinants, including those conferring resistance to fluoroquinolones.^{14,359}

Although most ESBL-producing bacteria are overtly resistant, the third-generation cephalosporins have minimal inhibitory concentrations (MICs) against some ESBL-producing organisms that fall into the high end of the susceptible range. Consequently, the incidence of ESBL-producing bacteria is underestimated when conventional MIC breakpoints for resistance are used. Growing numbers of reports, however, indicate that infections caused by organisms expressing susceptible MICs are clinically unresponsive to the third-generation cephalosporins.³⁸⁹ Many hospital microbiology laboratories therefore screen all *E. coli*, *Klebsiella*, and *P. mirabilis* clinical isolates for reduced susceptibility to ceftazidime and cefotaxime and alert the clinician accordingly.

The optimal therapy for infection caused by ESBL-producing gram-negative bacteria is not established. However, many authorities recommend a carbapenem for invasive ESBL-producing gram-negative bacterial infections.^{194,349,389}

Group 2 carbapenemases. The latter half of the 2000s witnessed the alarming spread of a new set of group 2, Ambler class A β -lactamases composed of carbapenemases, including the enzyme labeled *Klebsiella pneumoniae* carbapenemase (KPC)^{33,38,442} and advanced-generation group 2, Ambler class D OXA carbapenemases. This phenomenon has undermined the effectiveness of the class of antibiotics that had become the therapy of choice for previously encountered highly resistant organisms expressing AmpC β -lactamases and ESBLs.

KPC was first identified in an isolate of *K. pneumoniae* in the late 1990s from a patient in North Carolina.^{33,442} Because of the presence of KPC on readily transmissible and promiscuous genetic elements, organisms expressing this enzyme spread rapidly up the American Atlantic Coast. By the mid-2000s, KPC-bearing *K. pneumoniae* had caused a city-wide epidemic among hospitalized patients in New York City³⁸⁰; soon thereafter, the organisms were discovered throughout the United States (i.e., reported in 48 states and Puerto Rico) and globally.^{54,168,314,378} (<http://www.cdc.gov/hai/organisms/cre/TrackingCRE.html#CREmapNDM>).

Infections by KPC-expressing organisms have been identified primarily in critically ill adults in acute care hospitals^{129,148,344} and residents of long-term care facilities,^{64,354,515} without a significant representation in community-acquired disease. KPC-harboring organisms have been reported only sporadically in children,²⁶¹ but their presence in the pediatric age group may be underappreciated. A survey of resistant-organism colonization in a long-term care facility for neurologically impaired children and young adults in Ohio, for example, revealed an unrecognized high prevalence of KPC colonization among the residents.⁴⁸⁹

Virtually all reports document that infection by a KPC-bearing bacterium is associated with increased risk of death, with crude mortality rates frequently about 40% to 50%.^{188,261,447,483} In vitro data and clinical experience with adults have indicated that treatment with at least two agents is better than monotherapy, including regimens containing a carbapenem when the MIC is in the lower range of resistance.^{197,384,527}

The KPCs are extraordinarily broad-spectrum enzymes and are able to hydrolyze every class of β -lactam. Like other group 2 β -lactamases, the KPC enzymes have a serine-based active site for hydrolysis of the β -lactam ring. Their broad activity likely is the result of a more shallow position of the catalytic active site within the enzymatic cavity, rendering it more accessible to its antibiotic substrates.³⁸⁰ Their activity is resistant to most β -lactamase inhibitors; the only commercially available exception is the DBO non- β -lactam β -lactamase inhibitor avibactam.¹⁰⁴ Unfortunately, organisms expressing KPC are almost always multidrug resistant. Tigecycline, colistin, one or more aminoglycosides, and the β -lactam/ β -lactamase inhibitor combination of ceftazidime-avibactam are the antibiotics with the most consistent activity,^{104,314} although some strains have emerged as resistant to colistin.^{25,313}

The KPC family of enzymes is composed of multiple molecularly similar homologues that have been numbered sequentially as they have been discovered and characterized.^{227,380} Most disease has been caused by *K. pneumoniae* expressing KPC-2 and KPC-3. Dominant lineages of KPC-producing *K. pneumoniae* have been identified through multilocus sequence typing (MLST). The sequence type ST258 has been an especially prominent clone in the United States.^{148,227} ST258 has at least two distinct genetic clades, clade I and clade II. Although clade II is most often associated with KPC-3, clade I typically harbors KPC-2. Depending on KPC gene copy number or mutations in outer-membrane porin channels, the expressed level of carbapenem resistance can vary from susceptible to highly resistant.⁶² In any given geographic location, however, organisms expressing KPC can be found in a variety of *K. pneumoniae* sequence types and less frequently in species and genera of Enterobacteriaceae other than *K. pneumoniae*, indicating that KPCs have spread by person-to-person transmission of dominant clones and by bacteria-to-bacteria transmission of enzyme-bearing plasmids.^{227,243,283} The means of KPC acquisition in children may be of a more polyclonal epidemiology than adults in the same region.^{264,265,454}

The Ambler class D OXA β -lactamases, originally named for their ability to hydrolyze oxacillin, are a diverse group of enzymes that are particularly prominent in *Acinetobacter* and *Pseudomonas* spp.²⁴⁰ The first carbapenem-hydrolyzing OXA carbapenemase (OXA-23) was recovered from a clinical isolate in Scotland in 1985 before the introduction of carbapenems.³⁵⁵ The OXA β -lactamases, particularly OXA-23, OXA-48, and OXA-181 variants, can inactivate carbapenems to varying degrees. Their activity is resistant to most β -lactamase inhibitors; the only commercially available exception is β -lactam combination therapy with avibactam.¹⁰⁴ The OXA-carbapenem hydrolyzing enzymes are increasingly identified globally in a broadening array of genera, including those belonging to the Enterobacteriaceae.^{47,372} The OXA-48 enzymes, discovered in Turkey in 2001 in *K. pneumoniae*, hydrolyze penicillins at a high level and carbapenems at a low level, while sparing extended-spectrum cephalosporins; however, the coexpression of extended-spectrum β -lactamases results in broad-spectrum hydrolysis of all β -lactams.^{57,371,372,374}

Bush-Jacoby group 3 (Ambler class B) metallo- β -lactamases. The group 3 β -lactamases are composed of the metallo- β -lactamases (MBLs) (see Table 234.2).^{44,498} MBLs are genetically heterogeneous and structurally dissimilar to the serine β -lactamases. The MBLs are not suppressed by commercially available β -lactamase inhibitors, and the three subclasses (i.e., B1, B2, and B3) have different amino acid sequence homologies. Almost all clinically relevant, acquired MBLs belong to subclass B1. The active site requires the participation of zinc, and MBLs catalyze the hydrolysis of β -lactam drugs through a noncovalent mechanism; the zinc-dependent catalysis is inhibited by chelators such as ethylene diamine tetraacetic acid (EDTA). The active site itself is composed of a wide plastic groove that can accommodate many β -lactam substrates, including carbapenems. Some genes encoding MBLs are chromosomal (e.g., in *Stenotrophomonas*), but many are embedded in complex integrons that are inserted on transferable elements such as transposons and plasmids containing multiple antibiotic resistance genes.⁴⁹⁸

MBLs were originally identified in the middle to late 1980s in *P. aeruginosa*. The landscape dramatically changed in the 1990s and early 2000s with increasing reports of clinical infections and nosocomial outbreaks of gram-negative bacteria (including Enterobacteriaceae) harboring transferable genes encoding MBLs. The IMP (active on imipenem) and VIM (Verona integron encode D) types of MBLs were originally identified in Japan, Italy, and France and since have spread globally. VIM- and IMP-type MBLs continue to be prominent mechanisms of resistance in *A. baumannii* and *P. aeruginosa*.^{29,355} Additional transmissible MBL-harboring gram-negative bacilli have remained generally restricted to certain regions (e.g., SPM).^{138,380}

In 2008, attention to the MBL-producing Enterobacteriaceae epidemic increased with the discovery of a *K. pneumoniae* containing a new plasmid-borne MBL gene labeled New Delhi metallo- β -lactamase (NDM), identified in a Swedish patient who had previously received health care in India.²³⁵ The introduction into Enterobacteriaceae is thought to have originated from *A. baumannii*. Organisms harboring NDM genes subsequently were identified throughout the Asian subcontinent and

the United Kingdom, followed by global dissemination. Bacteria expressing NDM-type MBLs have been identified in patients in all age groups, including children, and in some instances have been the cause of community-associated infection.^{235,262} Plasmids carrying NDM-type MBLs are diverse in size and incompatibility group, and as in the case of other acquired carbapenemases, there frequently is concomitant carriage of multiple antibiotic-resistance determinants, including other β -lactamases and carbapenemases, and genes encoding resistance to fluoroquinolones, aminoglycosides, polymyxins, and other antibiotic classes,³²⁶ severely limiting therapeutic options.

For many of the β -lactamases described above, the degree of resistance exhibited by an organism expressing a specific enzyme frequently depends not only on its in vitro substrate specificity and kinetics but also on the amount of enzyme produced. Hyperproduction of β -lactamase usually is the result of some alteration of a controlling sequence or an increase in number of copies of the β -lactamase gene within the bacterium.^{134,342,519} High-level resistance results, and the susceptibility of the organism diminishes, with increasing numbers of bacteria. Consequently, the organism may appear clinically unresponsive to a β -lactam antibiotic if hyperproduction occurs in the context of a high-inoculum disease. In some circumstances, hyperproduction operates in concert with other mechanisms to produce a resistant phenotype. For example, some isolates of *E. cloacae* and *P. aeruginosa* have been rendered carbapenem resistant through a combination of hyperproduction of an AmpC β -lactamase, which normally is ineffective in hydrolyzing the carbapenems, and the simultaneous loss of the outer-membrane porin through which carbapenems traverse to reach the PBP.^{208,316,379}

Alteration of Penicillin-Binding Proteins

Clinical relevance. Two species of clinical importance to pediatricians express resistance to β -lactam drugs through the alteration of PBPs: penicillin-resistant *Streptococcus pneumoniae* and methicillin-resistant *Staphylococcus aureus* (MRSA). The precise clinical importance of penicillin resistance in *S. pneumoniae* remains unclear. Initially, their emergence was alarming because they frequently exhibited coincident resistance to other antibiotics, particularly trimethoprim-sulfamethoxazole (TMP-SMX) and the macrolides,^{93,97,189,395,473} which were commonly used to treat respiratory tract bacterial pathogens. Because the basis for this type of β -lactam resistance is akin to altered enzyme affinity, investigators posited in the mid-1990s that overcoming the apparent decrease in efficacy could be possible by increasing the dose of β -lactam used.^{212,288,289} On the basis of pharmacokinetic and pharmacodynamic calculations, it was predicted that a high-dose amoxicillin regimen (for outpatient therapy) or high-dose intravenous penicillin, ampicillin, or ceftriaxone (for inpatient therapy) would be curative in most nonmeningeal infections caused by *S. pneumoniae* with penicillin MICs of 2 to 4 $\mu\text{g/mL}$ or less, well above traditional nonsusceptible breakpoints. This prediction subsequently was confirmed by several observational studies of children with acute otitis media and for adults and children with pneumonia and bacteremia due to nonsusceptible *S. pneumoniae*.^{78,212,341,358,366,518,525}

In response to these observations, in 2008, the Clinical Laboratories Standards Institute, the organization responsible for defining susceptible and resistance MIC breakpoints in the United States, raised the penicillin MIC breakpoint designating resistance in nonmeningitis isolates from 2 $\mu\text{g/mL}$ or higher to 8 $\mu\text{g/mL}$ or higher,^{66,506} validating and encouraging the use of β -lactams in infections by organisms expressing penicillin MICs beneath the new breakpoint.

In contrast, in patients with pneumococcal meningitis caused by organisms with decreased penicillin susceptibility, there is a delay in sterilization of cerebrospinal fluid in the setting of standard treatment due to the difficulty in delivering drug into the central nervous system.^{144,253} The MIC breakpoint defining pneumococcal resistance in meningitis isolates therefore has remained unchanged ($>0.12 \mu\text{g/mL}$). Moreover, the current recommendations for empiric treatment of bacterial meningitis in infants and children consist of a combination of high-dose ceftriaxone or cefotaxime plus vancomycin⁴⁰ until the organism is identified and its antibiotic susceptibility is known.

The challenge of penicillin-resistant *S. pneumoniae* was also addressed by the introduction of the conjugated pneumococcal vaccines, first the 7-valent vaccine (PCV7), which became available in the United States

in 2000, and then the 13-valent vaccine (PCV13) in 2010. The serotypes included in the 7-valent vaccine accounted for most of the pneumococci responsible for invasive infection in the United States at that time.³¹ Coincidentally, the same serotypes were responsible for most of the penicillin resistance.

Surveys conducted by the Centers for Disease Control and Prevention (CDC) indicated that the incidence of invasive *S. pneumoniae* infection caused by penicillin-resistant strains decreased by more than 50% in the years immediately after the introduction of PCV7.⁴⁶⁸ The decrease was most pronounced among children younger than 2 years of age, but the herd immunity created by universal PCV7 immunization resulted in a reduction of pneumococcal infection in all age groups. This benefit was mitigated in part by increases in disease caused by resistant serotypes not included in the vaccine, most notably serotype 19A.^{17,180,236} In response to this phenomenon, PCV13 was developed, which included all seven serotypes represented in PCV7 plus six additional serotypes, including 19A, that accounted for most residual invasive and antibiotic-resistant pneumococcal infection encountered during the post-PCV7 era.^{346,467}

Surveys conducted in the 5 years after the introduction of PCV13 indicate a further reduction in antibiotic resistance among isolates from invasive and noninvasive disease,^{49,210,308,398,475} and most of the benefit resulted from reduction of infection caused by serotype 19A. Although residual resistance has been documented among non-PCV13 strains, no prominent resistant serotype has emerged.^{79,90} However, *S. pneumoniae* has proved facile in evading population immunity through serotype replacement,⁴⁵⁵ and assessment of the effectiveness of PCV13 in reducing invasive disease and penicillin resistance will need to be monitored throughout its use.

Like penicillin-resistant pneumococcus, the epidemiology of MRSA is fluid and constantly changing.^{92,458} Most MRSA isolates have been derived from a finite number of pandemic clones that have emerged in separate waves and have settled in different worldwide geographic regions.^{92,334,458} A given strain may predominate regionally, only to be subsequently replaced by another. Historically, MRSA was isolated first from hospitalized adult patients in 1961, and through clonal expansion, it became a prominent pathogen among critically ill patients during the ensuing decades. Two additional international clones of hospital-associated MRSA (HA-MRSA) emerged in the 1980s. By the early 2000s, more than one half of *S. aureus* infections in patients in ICUs in the United States were caused by MRSA.⁴³⁶

Compared with those in adults, MRSA infections occurred relatively infrequently among hospitalized children. In the mid-1990s, however, MRSA infections were identified among otherwise healthy children with no prior contact with hospitals or hospitalized patients, first in Western Australia and soon thereafter in the United States.^{163,184} These strains of community-associated MRSA (CA-MRSA) were molecularly distinct from all of the strains of MRSA previously identified in the hospital environment.

By the second decade of the new millennium, CA-MRSA had established a worldwide presence in children and adults.³²³ These organisms cause primarily skin and soft tissue infection but occasionally cause bone and joint infection, severe necrotizing pneumonia, and other invasive, deep tissue disease. CA-MRSA infections are especially common in populations inhabiting close quarters and engaging in skin-abrading activities, including athletes participating in competitive sports, military personnel, and prison populations.⁵⁰³ They increasingly are being identified in patients acquiring the infection in the hospital,^{181,375,430} blurring the epidemiologic distinctions that had once characterized HA-MRSA and CA-MRSA lineages.

Several systems have been proposed to categorize the principal MRSA clonal groups to help track their spread. The system established by the CDC is based on *Sma*I macrorestriction patterns of bacterial DNA visualized after separation by pulsed-field gel electrophoresis (PFGE). The PFGE types defined have been labeled USA100 through USA1200.^{186,292} Most American CA-MRSAs are included in the USA300 group, with a few derived from the USA400 and USA1100 groups.^{226,323} American HA-MRSA strains are derived mostly from the USA100 pulsed-field type.^{92,458}

MRSA strains also have been categorized by the MLST technique,¹⁰⁹ which distinguishes bacterial lineages based on polymorphisms found in seven housekeeping genes. Each PFGE type includes multiple MLSTs.

MLSTs are catalogued online (<http://www.mlst.net>), facilitating the publication of new strains and the tracing of established ones across the globe.⁹² The frequently encountered American HA-MRSA USA100 isolates belong primarily to MLST sequence type ST5, and the predominant USA300 belongs to ST8, but other MLST types are found within each of these groups of American isolates,⁸² and altogether different MLST types of MRSA dominate in other regions of the world.^{85,323} Further strain discrimination is achieved through polymorphisms of the *S. aureus* protein A gene (*spa*), which similarly are catalogued electronically (<http://www.spaserver.ridom.de>).

Mechanism of resistance. β -Lactam antibiotics must bind to PBPs to confer their activity, and alteration of the structure of PBPs results in diminished affinity for drug and in antibiotic resistance. The PBPs are a family of molecules on the bacterial cell surface. Although different species possess different numbers of PBPs, they historically have been designated numerically within each species by molecular weight and ordered largest to smallest.^{133,153} The molecules also have been categorized by function and sequence,⁴²¹ with the high-molecular-mass PBPs (historically named PBP1 and PBP2) responsible for transglycosylation and transpeptidation, the final two steps of peptidoglycan synthesis, and the low-molecular-mass PBPs contributing to cell wall remodeling and cell division.^{201,421,529} The β -lactams confer their activity by binding to the transpeptidase domain of the large-molecular-mass PBPs, interrupting peptidoglycan cross-linkage and reducing the tensile strength of the bacterial surface, which results in bacterial cell swelling and death.

Examination of PBP-mediated β -lactam resistance in *S. pneumoniae* and *S. aureus* exemplifies some of the features of this mechanism of resistance. Detailed investigations indicate that penicillin resistance in pneumococci is associated with alternations in PBP1A, 1B, 2A, 2X, and 2B; cephalosporin resistance has been correlated with structural abnormalities in PBP1A, 2A, and 2X.^{15,69,142,312} Confirmation that the resistant phenotype is related directly to structural abnormalities in various pneumococcal PBPs has been achieved through transformation experiments.^{15,69,142,312} In these studies, penicillin-susceptible strains are converted to penicillin-resistant strains by addition of amplified DNA encoding the putative resistant PBPs. Patterns of PBPs from resistant pneumococci vary considerably from geographic location to location, a finding indicating that PBP-related pneumococcal resistance probably arose independently in various parts of the world.¹⁵²

PBPs from penicillin-resistant *S. pneumoniae* contain blocks of amino acid sequences that are remarkably divergent from those seen in susceptible pneumococci. These sequences are homologous to those encoding for PBPs from other streptococcal species (e.g., *Streptococcus oralis*, *Streptococcus mitis*), a finding suggesting that the resistant pneumococci contain mosaic PBPs that arose after transformation and recombination of homologous genes from closely related bacteria.^{103,151,239} These sequences then developed point mutations that conferred resistance. A similar pattern of resistance blocks of amino acids has been identified in the PBPs of penicillin-resistant *Neisseria gonorrhoeae*, which appear to have originated from other *Neisseria* spp.¹⁵³ The degree of resistance conferred by a single mutated PBP is relatively small.^{133,142} Acquisition of multiple abnormal PBPs results in incremental resistance and, ultimately, in an organism that can survive routine β -lactam therapy.

In distinction to β -lactam resistance in *S. pneumoniae*, the resistance in MRSA is conferred by the predominance of a single abnormal PBP. Whether associated with the hospital or the community, all isolates of MRSA contain the *mecA* gene, a 2130-bp chromosomal sequence encoding the PBP2A, which has low affinity for β -lactam antibiotics, unlike the other staphylococcal PBPs.^{83,84} The *mecA* gene is carried on a mobile element designated the *staphylococcal cassette chromosome mec* (SCCmec) sequence. All MRSA strains contain an SCCmec complex, but their size and organization vary, allowing them to be grouped into eleven distinct SCCmec types, which are designated by roman numerals I through XI.^{186,333,530} Most hospital-acquired (HA)-MRSA strains contain SCCmec types I to III, whereas CA-MRSA strains characteristically harbor type IV.¹⁸⁶

In most HA-MRSA isolates, the SCCmec sequence contains resistance determinants in addition to *mecA*, including those conferring resistance to clindamycin, the aminoglycosides, and the fluoroquinolones.^{89,530} These organisms possess a selective advantage in ICUs, where exposure

to multiple classes of antibiotics commonly occurs. The CA-MRSA SCCmec type IV encodes a smaller SCCmec sequence usually lacking the multiple antibiotic-resistance genes found in their hospital-associated counterparts.^{89,530} Although a growing number of American strains of CA-MRSA are emerging resistant to fluoroquinolones and a small but growing number are resistant to clindamycin, only a few CA-MRSA bacteria express resistance to other antibiotics.^{291,470} However, USA300 CA-MRSAs express a number of virulence factors not common in other strains. Most notable among these is the Panton-Valentine leukocidin, possibly important for soft tissue breakdown and destruction, but a number of other virulence factors and altered genetic elements called *accessory genetic regulator (agr)* sequences controlling their expression have been identified.⁴⁷⁰ The smaller SCCmec sequences allow CA-MRSA to replicate more rapidly than HA-MRSA³⁵² because they can be maintained by the bacterium at a lower metabolic cost. The relatively small size of the CA-MRSA SCCmec sequences further enables efficient transfer to co-colonizing susceptible *S. aureus*.⁵³⁰

SCCmec elements likely originated in coagulase-negative staphylococci. Type IV SCCmec sequences, for example, have been identified in isolates of *Staphylococcus epidermidis* from the 1970s.⁵¹³ Sequences have been found in *S. epidermidis* and *Staphylococcus hominis* strains that contain the regulatory genes and insertion sequences of the SCCmec elements found in MRSA but that lack the *mecA* gene itself.³

Macrolides, Lincosamides, and Streptogramins

Clinical Relevance

The macrolides are compounds that contain 14-member (e.g., erythromycin, clarithromycin), 15-member (e.g., azithromycin), or 16-member (e.g., spiramycin) lactone rings. Their activity is directed primarily against gram-positive organisms and some gram-negative respiratory tract pathogens. In many bacteria, resistance to macrolides occurs concomitantly with that of the structurally unrelated lincosamides (including clindamycin) and streptogramin B families of antibiotics, two classes with activity primarily against gram-positive bacteria. Because these three families of antibiotics interact competitively for ribosomal binding, they probably are associated with the same ribosomal site.

Resistance to the macrolides was identified in staphylococcal species soon after the introduction of erythromycin. More recently, macrolide resistance in streptococcal pathogens, particularly *S. pneumoniae* and *Streptococcus pyogenes*, emerged and assumed major clinical importance. Macrolide resistance among pneumococci is a result of international dissemination of resistant clones and horizontal transmission of resistance determinants.^{131,416}

The late 20th century witnessed dramatic increases in the incidence of macrolide resistance in *S. pneumoniae* in many areas of the world.¹⁶⁷ In Southeast Asia, surveys indicated that almost 40% of pneumococcal isolates were resistant to all macrolide antibiotics, and samplings of organisms from Europe and the Western Hemisphere showed similar but less extreme trends.^{167,224} Perhaps most troubling, resistance to macrolides among pneumococci occurred frequently in isolates coexpressing resistance to penicillin and other oral antibiotics.^{97,185}

Similar to penicillin-resistant pneumococcus, the prevalence of macrolide-resistant *S. pneumoniae* was reduced during the first decade of the 21st century by the introduction and widespread administration of the conjugated pneumococcal vaccines, which include serotypes that most commonly express β -lactam and macrolide resistance.⁴⁷⁴ Studies performed in Atlanta, Georgia, before release of the 7-valent vaccine, for example, documented that 31% of pneumococcal isolates causing invasive disease were resistant to erythromycin.¹³⁰ Follow-up studies performed after the introduction of that vaccine recorded a drop in incidence of macrolide-resistant invasive pneumococcal disease by more than two thirds.⁴⁵⁰

Similar to *S. pneumoniae*, macrolide resistance in *S. pyogenes* has been unevenly distributed geographically.²¹⁷ By the start of the 21st century, most surveys in the Western Hemisphere, including the United States, indicated a prevalence of resistance less than 10%.^{143,340,399,508} Macrolide resistance in *S. pyogenes* is on average more prevalent in Europe, but the prevalence there also varies substantially from area to area, ranging in the mid-2000s from 3% in Norway²⁵⁸ to 13% in Belgium²⁷² and to more than 20% in Spain and France.^{24,356} Molecular

analysis of macrolide-resistant group A streptococcal isolates from geographically diverse regions suggested that the resistance genes were acquired multiple times by many lineages, some of which then disseminated worldwide.⁴⁰⁴

The increase in macrolide resistance has occurred concomitant with increased worldwide consumption of these compounds for respiratory tract infections beginning in the 1980s,^{22,68,185,429} a finding suggesting a biologic association between these two phenomena. A nationwide survey of macrolide susceptibility among pneumococcal isolates in the United States, for example, documented an increase in erythromycin resistance from 10.6% in 1995 to 20.4% in 1999, a time when the number of prescriptions for macrolides increased by 13% across the board and by 320% for pediatric patients.¹⁸⁵ Seppälä and colleagues⁴²⁹ reported an increase in resistance among *S. pyogenes* isolates in Finland from 5% in 1988 to 13% in 1990 after national macrolide consumption doubled during the 1980s. In response, a national campaign to reduce macrolide prescribing practices in Finland was launched in the early 1990s, after which macrolide resistance fell by one half.⁴²⁹ A similar campaign in Taiwan yielded similar results.¹⁷⁹

Although the epidemiologic trends in macrolide resistance are alarming, the clinical consequences of the increases in macrolide resistance among streptococci are largely unknown. The newer macrolide compounds achieve tissue and intracellular concentrations that are much higher than the recommended MIC breakpoints.^{110,328} Italian investigators, for example, reported a very high incidence of erythromycin resistance among group A streptococcal throat isolates, but neither clinical nor microbiologic failures were clearly associated with macrolide treatment.⁴⁸⁸ The macrolides do not distribute in high concentrations to the blood compartment, however, and several reports document poor outcomes when this class of drugs is used for bacteremic pneumonia caused by macrolide-resistant pneumococcus.^{223,268}

Despite these apparent shortcomings, the macrolides remain an attractive group of drugs because of their activity against atypical organisms and their safety profiles. As such, they have continued to attract the attention of the medicinal chemists. The second-generation drugs clarithromycin and azithromycin were introduced to overcome some of the resistance issues.⁴²⁸ They were followed by the short-lived introduction of the ketolides, telithromycin and cethromycin, which have not been thoroughly evaluated for pediatric patients but do confer resistance protection through their binding to a second ribosomal site, which renders them effective against organisms resistant to first- and second-generation macrolides.^{116,434}

Further structural engineering led to the synthesis and clinical evaluation of solithromycin, the first of the fluoroketolides.¹¹⁷ Its introduction addressed a number of deficiencies of its predecessors, including a pharmacokinetic profile that provides antimicrobially significant concentrations of drug in plasma, tissues, and intracellularly and a pharmacodynamic profile that precludes many of the limiting side effects that hampered the earlier ketolides. It also has a third ribosomal binding site determined by the fluorine domain that ensures activity against organisms resistant to other macrolide antibiotics.

Mechanism of Resistance

Two principal resistance phenotypes to macrolides and related antibiotics have been detected. The first, the MLS_B phenotype, is characterized by resistance to all macrolides, regardless of the size of the ring, and to the lincosamides and the type B streptogramins. Most organisms expressing the MLS_B phenotype remain susceptible to the combination streptogramins.^{154,424} The second phenotype, the M phenotype, is associated with resistance to the 14- and 15-member macrolides (including erythromycin, azithromycin, and clarithromycin) but not those with 16-member rings. The degree of resistance to the affected macrolides is lower on average than that seen with MLS_B resistance. In organisms with the M phenotype, susceptibility to clindamycin is preserved.^{284,460}

Most MLS_B resistance results from methylation of the 23S ribosomal RNA (rRNA) in the 50S subunit of the bacterial ribosome within the peptidyltransferase circle in domain V.^{88,196,469,509} The methylases are encoded on transposons, with sequences found on plasmids and in the bacterial chromosome.¹³⁷ Methylation of the 23S rRNA is encoded by a family of related genes called *erm* (i.e., erythromycin resistance

methylases).^{88,196,469,509} Historically, these methylases have been described and named in a haphazard fashion, although some investigators have proposed renaming many of the enzymes using a classification scheme based on genetic homology.⁴⁰¹

Methylation is both inducible and constitutively expressed. Unlike many other inducible antibiotic-resistance factors, the mechanism of MLS_B resistance induction is at the level of translation rather than transcription.⁵⁰⁷ In the uninduced state, the leader sequence of the mRNA encoding ErmC, one of the methylases found in *S. aureus*, forms two stem loop structures that stall the ribosome's movement along the message, thereby preventing synthesis of the methylase enzyme. The attachment of erythromycin to the ribosome leads to a conformational alternation of the leader sequence that uncovers the appropriate ribosomal binding sites and allows the stalled ribosomes to proceed to translation.⁵⁰⁷

Inducible macrolide resistance is detected in the clinical microbiology laboratory by the double-disk diffusion test (D test). In this assay, an erythromycin disk and a clindamycin disk are placed side by side on a lawn of the test organism. Induction of clindamycin resistance in the presence of erythromycin manifests by increased growth of bacteria on the erythromycin side of the clindamycin disk, producing a D-shaped zone of inhibition. Through the 1990s, greater numbers of *erm*-containing bacteria produced the rRNA methylase constitutively, a consequence of mutation of the leader sequence.^{99,465}

In the mid-1990s, macrolide resistance mediated through a genetically transferable efflux pump was identified.⁴⁶⁰ Most organisms expressing the M phenotype are resistant through this mechanism. Most macrolide-resistant pneumococci in North America express the macrolide efflux pump, and much of the expansion of macrolide resistance that occurred through the 1990s was the result of the appearance of organisms exhibiting this mechanism.^{185,204,256,468} A family of related genes (*mef*) encodes the macrolide efflux pumps. The *mef* genes are included on transposons encoding associated functions, particularly an adenosine triphosphate (ATP)-binding protein.^{130,131,137,284} As expected, ribosomes isolated from organisms resistant through *mef* genes bind to macrolide antibiotics as readily as do ribosomes from susceptible organisms. Radiolabeled erythromycin is excluded from the intracellular space in *mef*-positive bacteria, a phenomenon that is reversed by compounds that poison ATP-dependent pumps.⁴⁶⁰

Mechanisms of macrolide resistance besides rRNA methylation and efflux pumps have been identified but are uncommon. Some organisms modify the antibiotic by hydrolysis, acetylation, phosphorylation, or esterification.⁴⁰¹ Some evidence indicates that some erythromycin resistance is caused by altered ribosomal proteins and results in the production of ribosomes with diminished affinity for drug.⁶⁵

Trimethoprim and Sulfamethoxazole

Clinical Relevance

The combination antibiotic TMP-SMX inhibits bacterial folate synthesis at two successive steps. This mechanism accounted for its broad activity against a wide variety of gram-positive and gram-negative bacteria when it was first introduced in 1968. Despite the dual activity of this combination, resistance to TMP-SMX has risen steadily during the decades of its use and is now common. Acquisition of resistance is potentiated by recent exposure to TMP-SMX.^{115,449,517} When resistance occurs, the MIC expressed usually is very high,^{183,182} and the affected organisms frequently are coresistant to multiple other classes of antibiotics.

TMP-SMX resistance is sufficiently widespread that it precludes the use of the drug as a first-line antibiotic in clinical circumstances in which it was formerly the agent of choice, such as respiratory tract infections and *Shigella*-associated dysentery. Its utility in urinary tract infection (UTI) also may be limited when the community prevalence of TMP-SMX resistance is sufficiently high. Ironically, its continued activity against CA-MRSA has rejuvenated the use of TMP-SMX among many practitioners as the incidence of infections caused by CA-MRSA organisms has mushroomed.

Respiratory tract infections: otitis media and pneumonia. The frequency of TMP-SMX resistance in organisms causing respiratory tract infections has increased significantly. Among *S. pneumoniae* organisms, resistance to TMP-SMX was identified during the 1990s in many geographic

locations, with resistance detected in 12% to more than 50% of isolates.^{97,167,178,189,277,347,456} A worldwide survey conducted in the late 1990s found the highest incidence of TMP-SMX pneumococcal resistance in the Asian Pacific region and in Latin America.¹⁶⁷ In surveys of US isolates, TMP-SMX resistance is the most common resistance phenotype found in *S. pneumoniae*,⁵¹¹ although the incidence of resistance varies widely from region to region.⁹⁶

TMP-SMX resistance is strongly associated with resistance to other classes of antibiotics commonly used in respiratory tract infections, particularly penicillin and the macrolides. Among other organisms implicated in respiratory tract infections, TMP-SMX resistance also has been documented with increasing frequency in *H. influenzae*, to which resistance ranges from 7% in Finland²⁷⁷ to more than 50% in Taiwan.¹⁷⁸ The susceptibility of *M. catarrhalis* to TMP-SMX varies little from region to region. Although most *M. catarrhalis* organisms remain susceptible to TMP-SMX, the MICs cluster near achievable respiratory tract concentrations.¹⁸⁹

The clinical consequences of TMP-SMX resistance in respiratory tract pathogens are not well defined. For example, direct evidence of the association between isolation of a TMP-SMX-resistant organism from the middle ear and failure of therapy by TMP-SMX in acute otitis media is lacking, but the association is assumed to exist. The issue of the clinical relevance of TMP-SMX resistance in respiratory tract infections is particularly pressing in developing countries, where World Health Organization (WHO) guidelines recommend TMP-SMX as a first-line agent for pneumonia. A comparison of amoxicillin and TMP-SMX for treating pneumonia in Pakistan demonstrated superiority of amoxicillin in producing clinical cure, but treatment failure was not associated with resistance in the infecting organism.¹⁵⁷ These data and others^{220,390,406} support the continued use of TMP-SMX therapy of pneumonia in the developing world.

Shigellosis. Resistance of *Shigella* spp. to TMP-SMX rose dramatically during the 1980s in many parts of the world, including Bangladesh,²¹ Thailand,⁶⁹ Somalia,⁵⁸ Israel,¹⁰ and Canada.¹⁵⁶ In these surveys, the incidence of disease from TMP-SMX-resistant *Shigella* increased twofold to threefold, accounting for more than one half of the isolates. By 1998, more than 90% of *Shigella* organisms in Thailand¹⁶⁹ and *Shigella* cultured from patients with acquired immunodeficiency syndrome (AIDS) in Kenya²³⁴ were resistant to TMP-SMX. Many of these *Shigella* organisms express extraordinarily high levels of resistance, with MICs to TMP exceeding 1000 µg/mL.

In the United States, TMP-SMX resistance among *Shigella* isolates initially was confined to closed populations.¹⁴⁴ A survey in Oregon, however, indicated that by the late 1990s the incidence of TMP-SMX resistance among *Shigella* isolates in that state approached 60%. Resistant isolates were found disproportionately frequently in migrant workers traveling from Mexico and other areas of Latin America,³⁹⁶ a finding emphasizing the importance of geographic spread of resistance in modern society. Subsequent surveys performed by the CDC in the early 2000s revealed that TMP-SMX-resistant *Shigella* had spread nationwide, with the prevalence highest in the East and West.⁴³⁸ The incidence of TMP-SMX resistance in *Shigella* mirrors the increased TMP-SMX resistance among other enteric species,¹⁴⁴ notably *Salmonella*.¹

TMP-SMX resistance in *Shigella* is virtually always borne on conjugative plasmids, and these plasmids frequently contain resistance determinants to several other antibiotic classes.^{58,144,234,254,438,485} Coresistance to four or more unrelated antibiotics, including β-lactams, chloramphenicol, tetracycline, and the aminoglycosides, is a common finding. Molecular analyses in a given geographic environment usually indicate fluid epidemiology, with multiple dominant chromosomal genotypes containing a variety of resistance plasmids.^{37,254}

Urinary tract infections. Through the 1990s and 2000s, TMP-SMX resistance in urinary tract isolates of *E. coli*, the most prominent pathogen implicated in UTIs, rose to between 15% and 25% in the developed world and to as high as 60% in nonindustrialized countries.^{147,149,216,275,532,533} Studies in the 1980s indicated that TMP-SMX-resistant *E. coli* can be transmitted to household contacts.⁴⁰⁸ Although urinary concentrations of TMP and SMX are several-fold higher than concomitant concentrations in serum, resistance to TMP-SMX nonetheless is associated with treatment failure in UTIs. Bacterial and clinical response rates to TMP-SMX are 80% to 95% for cystitis and pyelonephritis caused by

susceptible organisms, but the response falls to approximately 50% when the infecting agent is resistant to TMP-SMX.^{287,463}

Considering all urinary tract pathogens together, the clinical and microbiologic response to TMP-SMX is almost equivalent to comparator agents, and most experts continue to recommend this drug as a first-line therapy for uncomplicated UTIs based on its low cost.^{118,147,175} Analyses have indicated that the total expense of treatment of UTIs with TMP-SMX begins to exceed that incurred by therapy with more expensive antibiotics when the community TMP-SMX–resistance rates of urinary pathogens exceed approximately 20% as a result of the additional expense of clinical treatment failure.^{242,463} Alternatives to TMP-SMX also should be considered when the patient possesses risk factors for acquisition of infection with a TMP-SMX–resistant strain, such as recent hospitalization, diabetes, or therapy with TMP-SMX within the previous 3 months.^{146,175}

Community-associated methicillin-resistant *Staphylococcus aureus*. Despite the explosive emergence of methicillin resistance in community-associated *S. aureus* infections in the latter half of the 1990s, these organisms have remained almost uniformly susceptible to TMP-SMX.^{39,211,309} Most infections caused by CA-MRSA are skin and soft tissue infections that can be treated without hospitalization, and TMP-SMX offers an inexpensive, oral therapeutic option in this setting. The clinical effectiveness of TMP-SMX in CA-MRSA infection relative to other oral agents is uncertain; whether any antibiotic is superior to incision and drainage, particularly in mild cases, is not clear.^{302,386,451} Accumulated reports, however, support the use of TMP-SMX as a therapeutic option for purulent cellulitis when CA-MRSA is suspected or confirmed.^{300,451,462}

Mechanisms of Resistance

In susceptible bacteria, TMP-SMX inhibits sequential steps in the de novo synthesis of folate (Fig. 234.3). SMX inhibits the enzyme dihydropteroate synthetase (DHPS), which catalyzes the conversion of *para*-aminobenzoic acid to dihydrofolate. TMP inhibits the next enzyme in the pathway, dihydrofolate reductase (DHFR), which catalyzes the conversion of dihydrofolate to tetrahydrofolate. The resulting depletion of folate in the bacterium interrupts the synthesis of critical cellular substrates, including purine nucleotides.⁴⁰⁵ Eukaryotic DHFR is resistant to the activity of the sulfonamides, and eukaryotic cells do not express DHPS activity at all, accounting for the selective activity of these drugs against bacteria.^{182,183,405}

The principal mechanism of resistance to TMP-SMX is alteration of the target enzymes. Altered genes for DHFR with reduced susceptibility to TMP have been identified on the chromosomes of intrinsically resistant organisms from a variety of species³⁶⁷ and on mobile elements. Many of the transferable resistance genes are encoded on transposons that can shuttle between plasmids and chromosomal DNA. Approximately 20 mobile *dhfr* resistance genes have been identified.¹⁸³ Resistance usually is conferred by a single-point mutation that results in a disruption of the three-dimensional conformation of DHFR, thereby interrupting a hydrogen bond normally available for binding the antibiotic but leaving the affinity for its natural substrate intact.^{81,183,367} These structural changes can occur in concert with mutations of controlling sequences and lead to overproduction of the altered DHFR.³⁶⁷ Similarly, sulfonamide resistance usually is the result of mutated *dhps* genes. Transmissible mutations of *dhps* conferring sulfonamide resistance in Enterobacteriaceae have been designated *sul1*, *sul2*, and *sul3*.

In TMP-SMX–resistant *Neisseria meningitidis*, the abnormal chromosomal *dhps* sequence is different compared with that found in susceptible isolates over a large portion of the gene, a finding implying that resistance resulted from a recombination event after horizontal transfer from an unrelated *Neisseria* spp.³⁸⁵ Similar recombination events may account for sulfonamide resistance in pneumococcus. In other species, the abnormal *dhps* gene is the result of a single amino acid mutation, and the resistance gene is encoded on a conjugative transposon,³³⁹ which frequently is linked to a *dhfr* resistance gene.¹⁸³

Some organisms, particularly *P. aeruginosa*, are intrinsically resistant to TMP-SMX on the basis of the expression of multidrug efflux pumps.²³⁰ The same pumps are responsible for resistance to a wide variety of other antibiotics, including fluoroquinolones, chloramphenicol, and β -lactams. Homologous pumps occasionally have been identified in other gram-negative species. In some isolates, the mechanism of resistance

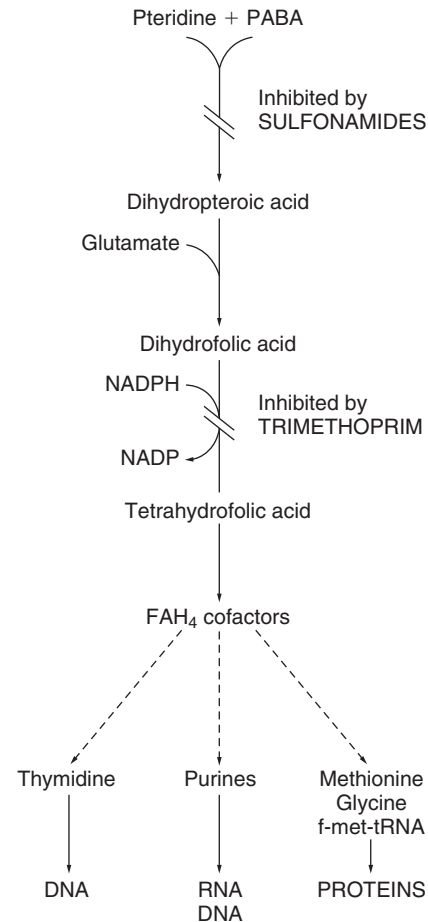

FIG. 234.3 Trimethoprim-sulfamethoxazole inhibition of de novo folate synthesis. *NADP*, Nicotinamide adenine dinucleotide phosphate; *NADPH*, reduced form of nicotinamide adenine dinucleotide phosphate; *PABA*, *para*-aminobenzoic acid.

to TMP-SMX is not attributable to any of those previously listed and remains undefined.³³⁹

Aminoglycosides

Clinical Relevance

The aminoglycosides are parenteral antibiotics that are employed primarily for serious infections in hospitalized patients. Resistance to aminoglycosides is encoded on transmissible elements that have disseminated throughout the world among gram-negative and gram-positive pathogens. Among gram-negative species, resistance to the aminoglycosides varies widely according to geographic location,^{423,487} but it is especially prevalent among hospital-acquired bacteria that are multidrug resistant.^{13,207,310}

Surveys of international hospital isolates conducted throughout Europe and North America in the late 1990s and the first decades of the 2000s indicated resistance rates of 1% to 15% for enteric bacilli and 10% to 50% for non-lactose fermenters.^{28,120,164,207,299,321,412,423} In most cases, the incidence of resistance was lowest to amikacin. Few data exist for the endemic incidence of aminoglycoside resistance in gram-negative organisms specifically among hospitalized children. However, outbreaks caused by gram-negative rods resistant to aminoglycoside have been reported from numerous neonatal ICUs since the early 1980s.^{71,293,419} Not surprisingly, fecal colonization with aminoglycoside-resistant bacilli is an uncommon finding among healthy persons.^{248,335,381}

Although the aminoglycosides have no utility in the treatment of infections with gram-positive organisms when used alone, they improve bacterial killing *in vitro* when they are employed in combination with cell wall-active agents. For this reason, these drugs frequently are added to β -lactam agents or vancomycin in the treatment of difficult or persistent infections caused by *S. aureus*, coagulase-negative staphylococci,

or enterococci. However, resistance to aminoglycosides has been documented in all these gram-positive microorganisms. Surveys in Europe indicated 20% to 30% resistance to aminoglycosides among hospital isolates of *S. aureus*.⁴²³ The occurrence of aminoglycoside resistance is much higher among MRSA isolates than in bacteria that are methicillin susceptible.^{87,120} Aminoglycoside resistance in hospital acquired coagulase-negative staphylococci also is a common finding.^{95,228,423}

Since the 1970s, proliferation of enterococci that express MICs to the aminoglycosides exceeding 2000 µg/mL has occurred, rendering the organisms resistant to all synergistic effects when the aminoglycosides are used with a cell wall-active agent.^{108,351} Such high-level aminoglycoside resistance has been recorded in approximately 30% of enterococcal samples from hospitals throughout the world.^{269,528} Organisms expressing high-level aminoglycoside resistance frequently also test highly resistant to ampicillin.³⁵¹ High-level aminoglycoside resistance is a common finding in vancomycin-resistant enterococci, especially those identified in the United States.²⁶⁹

Mechanism of Resistance

The aminoglycosides are hydrophilic sugars composed of one to four rings, with amino groups substituting some of the hydroxyl groups at sites that vary from drug to drug. The amino groups render the drugs polycationic and allow them to bind with high affinity to selected sequences of nucleic acid.³⁹⁴ The antibacterial activity of these drugs results from their binding to the A-site on the 16S ribosomal RNA responsible for the matching of tRNA and mRNA in the process of protein synthesis. Interaction with aminoglycosides results in a conformational change of the ribosome that results in diminished proofreading and missense translation.^{19,233,388,394} The affinity of the aminoglycosides for ribosomal RNA is 10-fold higher in prokaryotes than in eukaryotes.³⁹³

The principal mechanism of resistance to the aminoglycosides is through the expression of aminoglycoside-modifying enzymes.^{19,388} The modifications conferred by these enzymes result in altered electrostatic qualities of the antibiotic and consequent reduced ability to interact with rRNA. Many of these enzymes are encoded on transposons that reside in plasmids along with other resistance determinates.

Three groups of modifying enzymes have been identified: acetyltransferases (AAC), nucleotidyltransferases (ANT), and phosphotransferases (APH), each of which adds its respective moieties to selected side groups of the aminoglycoside sugar rings (Fig. 234.4).^{19,233,388,432} Most members of each group of modifying enzymes share structural homologies, with minor amino acid variations resulting in specific substrate profiles.⁴³²

In the most commonly used nomenclature scheme, the enzymes are designated by the site they modify, by the resistance profile they confer, and by a lowercase letter identifying the specific enzyme within

each group.^{19,388} For example, AAC(6′)-IIa denotes an AAC that substitutes an acetyl group for the amino group at the 6′ site of the aminoglycoside, with a resulting resistance pattern II (including resistance to gentamicin, tobramycin, and sisomicin but not amikacin in this case); the letter *a* at the end denotes the specific enzyme within the group of AAC(6′)-II molecules. Several enzymes within the AAC(6′) group in particular have formed fusion proteins with other aminoglycoside-modifying enzymes through recombination events³⁸⁸; AAC(6′)-Ie-APH(2′′)-Ia, for example, expresses AAC and APH activity. In the mid-2000s, a plasmid-borne AAC enzyme (i.e., AAC[6′]-Ib-cr) was characterized that could acetylate moieties on ciprofloxacin and norfloxacin as well as on aminoglycosides.⁴⁰³ Although the degree of fluoroquinolone resistance conferred by this enzyme is small, coexpression of other quinolone resistance determinants results in clinically relevant reduction in susceptibility.⁴⁰³

In the early 2000s, acquired 16S ribosomal RNA methyltransferases were discovered that interfered with the binding of aminoglycosides to the A-site, resulting in high-level resistance.⁹⁸ Two families of 16S rRNA methylases are defined. The N7-G1405 16S-RMTases have multiple subcategories and confer resistance to gentamicin, tobramycin, and amikacin but not to neomycin. The less frequently encountered N1-A1408 16-RMTase confers resistance to all aminoglycosides. These methylases have been identified in a wide variety of enteric and nonenteric gram-negative pathogens. They characteristically coreside on mobile elements encoding multiple other resistance determinants, including the ESBL, KPC, and especially NDM broad spectrum β-lactamases.¹⁶⁴ The 16S rRNA methylases have been found in isolates from around the globe, but they appear to be most frequently encountered in Southern and East Asia; their epidemiologic impact is not fully defined.^{98,164,376}

Moderate-level resistance to the aminoglycosides has been achieved by some bacteria through decreased intracellular concentration of drug by reduced permeability of the cell membrane or efflux.^{19,303} These mechanisms have been identified most frequently in *Pseudomonas* spp. Mutations of ribosomal proteins also have been associated with aminoglycoside resistance.^{19,388} Modifications of the ribosomal A-site binding sequences have been identified only rarely as a mechanism of resistance to aminoglycosides.¹⁹ The sequences involved in aminoglycoside binding likely are sufficiently critical to the survival of the organism that mutations within this site usually are fatal.²³³

Glycopeptides

Clinical Relevance

Vancomycin is one of two glycopeptides available for clinical use. The second, teicoplanin, is licensed in Europe but not the United States. Since the late 1980s, the prevalence of vancomycin resistance in organisms belonging to the genus *Enterococcus* (i.e., vancomycin-resistant enterococci [VREs]) has risen alarmingly. VREs frequently are highly resistant to many other antibiotics.

VREs appeared coincident with an increased use of vancomycin in the United States and the use of the glycopeptide avoparcin as a growth promoter in animal feed in Europe, a practice banned by the European Union in 1997.³¹⁵ The incidence of VREs colonization and disease is much more prevalent in the United States than in other areas of the world,^{94,269} but these organisms occur globally.^{177,512} Between 10% and 20% of US enterococcal isolates investigated in surveys in the late 1990s and early 2000s were resistant to vancomycin.^{94,269} Disproportionate numbers of VREs in the United States are found in patients hospitalized in ICUs in large urban medical centers, especially people with prolonged hospitalizations and severe disease.^{159,270,433} A high incidence of VREs is seen among oncology patients,²⁸² transplant recipients,^{106,294} and those with chronic renal failure who are receiving dialysis.^{11,471,492} Some surveys have documented VREs among adults in chronic care facilities, who exported the organism into the community after acquisition in an acute care setting.⁴⁷⁸ In contrast, the prevalence of VREs is relatively low in US hospitals serving rural areas.⁴⁵³

Surveys of European centers also indicate a concentration of VREs in ICUs, although in smaller numbers compared with the United States.^{413,425} The occurrence of VREs in Europe varies widely from country to country. In 2010, the proportion of blood isolates of *E. faecium* that were resistant to vancomycin ranged from 0% in Sweden and Finland

FIG. 234.4 Sites of modification on kanamycin B by various aminoglycoside-modifying enzymes. The arrows point to the sites of modification by the specific enzymes acetyltransferases (AAC), phosphotransferases (APH), and nucleotidyltransferases (ANT).

to more than 20% in Portugal, Greece, and Ireland.⁵⁹ VREs also have been reported in Asia and Latin America but at rates approximately one half of those found in the United States.⁵⁹

The genetic machinery conferring vancomycin resistance in enterococci is complex, and resistance does not develop *de novo* by spontaneous mutation under antibiotic pressure.³¹⁵ The initial event in the appearance of VREs in a given unit is the importation of the resistant organism into the environment. The association between antecedent treatment with vancomycin and acquisition of VREs has been documented by many,^{123,433} but not all investigators.^{56,101} Some researchers have established a stronger connection between the appearance of VREs and the use of extended-spectrum cephalosporins^{30,337} and antibiotics with potent antianaerobic activity,^{100,270} but it is likely that exposure to any broad-spectrum antimicrobial increases the risk of VREs acquisition.³⁰¹

Horizontal transmission of VREs is prominent in any closed environment and may outweigh antecedent antibiotic exposure as the principal determinant for acquisition.^{30,159} Patient-to-patient spread in an ICU, presumably through the hands of caregivers, has been documented repeatedly, as has contamination of the immediate environment of the VRE-positive patient.^{301,337,439} The most significant risk factor for acquisition of a VRE may be the number of neighboring patients colonized with the organism at the same time.^{12,30}

In many American ICUs, multiple clones of VREs are present at any given time. Some are imported into the unit, and others spread after admission has occurred,³³⁷ rendering control and containment difficult to achieve. Extreme barrier isolation precautions, including surveillance for VREs on admission to a unit, single-room isolation with dedicated medical instruments, and strict use of gowns and gloves, frequently are necessary to contain a VRE after it has established an endemic presence, and even these measures may not be entirely effective.^{199,238,439}

With some exceptions,^{141,482} VREs have been less of a threat to pediatric patients than to adults, despite the wide use of vancomycin among hospitalized pediatric patients and their geographic proximity in many hospitals to sick adults colonized with the organism. Several VRE outbreaks in the newborn nursery have been reported,^{245,273} but they have resulted primarily from dissemination of a single clone within the unit and have been successfully eradicated with implementation of relatively simple barrier isolation and cohorting measures.

In the latter half of the 1990s, a second phenomenon involving reduced susceptibility to vancomycin was identified: vancomycin-intermediate *S. aureus* (VISA).^{122,443} These organisms express MICs to vancomycin in the intermediate range of approximately 8 µg/mL. Virtually all of these isolates are coresistant to methicillin, but several have retained susceptibility to numerous other antimicrobial agents. VISA isolates have been identified primarily in patients who have been treated with prolonged courses of vancomycin for MRSA infection. Disproportionate numbers of these patients have been undergoing dialysis.⁴⁴³ Cure of the VISA-infected patient has been difficult but

achievable with high doses of vancomycin in combination with other antibiotics.^{122,443}

In 2002, the first two cases of true vancomycin-resistant *S. aureus* (VRSA) in the United States were reported, one from Michigan and the other from Pennsylvania (MICs to vancomycin were >128 µg/mL and 32 µg/mL, respectively).²⁵⁵ Both patients were suffering from chronic foot ulcers, from which the organisms were isolated. In both instances, the bacteria were susceptible to alternative agents, and the patients remained clinically stable. The potential for VRSA to emerge as a major public health hazard is substantial, but subsequent cases have been rare.^{255,499} Almost all VRSA organisms have been derived from MRSA lineages associated with hospital-acquired strains, particularly USA100, but in contrast to other HA-MRSAs, surveys of close contacts of the index cases have failed to detect person-to-person transmission.^{255,499}

Mechanisms of Resistance

By 2015, eight genotype clusters of vancomycin resistance in enterococci had been defined, labeled VanA through VanE and VanG, VanL, VanM, and VanN, each associated with phenotypic nuances.^{73,301,315} The genotypes vary in the species of enterococci affected, the relative resistance conferred to vancomycin and teicoplanin, and whether they are inducible or constitutively expressed (Table 234.3). The VanC phenotype is distinct from the others in that it is an intrinsically expressed, species-specific product of *Enterococcus gallinarum*, *Enterococcus casseliflavus*, and *Enterococcus flavescens*.³¹⁸ The other vancomycin genotypes are acquired, although several are not readily transferable (see Table 234.3). Most human isolates are derived from the VanA group.

In susceptible bacteria, the glycopeptides are large molecules that interfere with cell wall peptidoglycan synthesis at a point proximal to that targeted by the β-lactam antibiotics. Specifically, the synthesis of peptidoglycan in vancomycin-susceptible bacteria includes the incorporation of a D-alanyl-D-alanine dipeptide onto the carboxyl end of the growing glycopeptide chain to form a pentapeptide precursor. The pentapeptide is translocated from the cytoplasm to the outer surface of the bacteria.⁷³ The D-Ala-D-Ala carboxyl-terminal end of the pentapeptide is critical for the continued synthesis of the peptidoglycan chain and ultimately for peptidoglycan cross-linking and the formation of a stable cell wall. Vancomycin, which never enters the cell, binds to the D-Ala-D-Ala moiety of the pentapeptide through several hydrogen bonds along the outer surface of the cell wall,¹⁶ blocking synthesis of the remaining macromolecule.

The molecular basis for vancomycin resistance results from the complex, coordinated interactions of multiple genes that usually are on a single genetic element. These interactions have been defined best for the VanA phenotype, although genetic homologues are found in organisms expressing the other vancomycin-resistant phenotypes. The genetic machinery for VanA resides on the 10,851-bp transposon Tn1546.^{9,496} The molecules central to conferring the resistant phenotype

are encoded by the contiguous genes labeled *vanH*, *vanA*, and *vanX*, all of which are essential for expression of vancomycin resistance.

The *vanA* gene encodes a ligase that, unlike the native enterococcal ligase, produces an abnormal D-alanyl-D-lactate dimer over the normal D-alanyl-D-alanine.⁴¹ This process results in the formation of the peptidoglycan precursor uridine diphosphate–MurNAC–L-Ala–D-Glu–L-Lys–D-Ala–D-Lac, the carboxyl terminus of which has profoundly reduced affinity for vancomycin.^{42,59} The homologous ligase in VanC-, VanE-, and VanG-expressing organisms synthesizes D-Ala–D-Ser (see Table 234.3) with similar consequences,^{73,315} although the degree of resistance conferred by formation of D-Ala–D-Ser is less profound than that conferred by D-Ala–D-Lac. VanH catalyzes the reaction taking pyruvate to D-Lac and increases the availability of this substrate to VanA for production of the D-Ala–D-Lac dimer.⁴² The *vanX* gene and a second gene labeled *vanY* encode a cleaving enzyme for the D-Ala–D-Ala dipeptide, reducing the natural cellular substrate for the D-Ala–D-Ala by adding enzyme and resulting in greater relative incorporation of D-Ala–D-Lac into the peptidoglycan precursor.³⁹⁷

Between 2002 and 2016, 14 adult American patients were described who had fully vancomycin-resistant MRSA infections, and small numbers of other VRSA were detected in South Asia and Europe.²⁵⁵ Among those VRSAs that were molecularly analyzed, the isolates harbored the TN1546 transposon found in VREs,^{255,499} and several patients were coincidentally colonized with VREs.^{255,499} This finding indicates that true VRSA likely results from the conjugal transfer of the vancomycin-resistance transposon from VRE to MRSA, a phenomenon that can be replicated in vitro.³²⁴

VISA isolates do not contain the resistance genes found in VRE; these isolates acquire unusual extracellular material around the cell wall as detected by electron microscopy.^{43,443} This layer represents accumulated peptidoglycan with reduced levels of cross-linking, exposing an excess of D-Ala–D-Ala moieties that bind to vancomycin before it can reach the cell wall.⁴⁹⁷

Other vancomycin-resistance phenomena in *S. aureus* have been described and include those in which subpopulations express MICs twofold to eightfold higher than those in the parent population (i.e., heteroresistance)^{122,209} and those in which *S. aureus* can be inhibited but not readily killed by vancomycin (i.e., tolerance).²⁸⁵ Some investigations indicated that isolates of *S. aureus* expressing vancomycin heteroresistance develop into VISA with continued exposure to the drug.⁴⁹⁷

Issues surrounding reduced susceptibility to vancomycin have been partially addressed by the introduction of the lipoglycopeptides (Table 234.4). These agents have a hydrophobic moiety added to the glycopeptide core, which anchors the agents into the cell wall close to the peptidoglycan molecular target, accounting for their increased potency compared with vancomycin.⁵³¹ In the case of oritavancin and telavancin, the interaction with the bacterial cell surface also alters cellular permeability and disrupts membrane potential, increasing their antibacterial effect. The lipoglycopeptides have very good activity against VISA and some of the infrequently encountered genotypes of VRE. Only oritavancin has activity against the *vanA* genotype⁵³¹; hence, it exhibits in vitro activity against this most common VRE genotype and against VRSA (see Table 234.4).

Resistance to oxazolidinone daptomycin, and ceftaroline. Two antibiotics introduced in the early 2000s, linezolid and daptomycin, were developed to address the increasingly important problem of antibiotic-resistant gram-positive pathogens, especially VRE and MRSA. In both instances, the antibiotic represented a novel class of molecules, and it was hoped that resistance would be slow to develop. The fifth-generation

cephalosporins, ceftaroline and ceftobiprole (the latter is not licensed in the United States), were introduced several years later to provide additional therapies, particularly for MRSA. Antibiotic resistance was identified for all of the newer classes of antibiotics after their introduction.

Oxazolidinones. Linezolid, the first of the oxazolidinone antibiotics, has activity against all important human gram-positive pathogens, including MRSA, VISA, coagulase-negative staphylococci, and VRE. Gram-negative organisms are intrinsically resistant to linezolid because they express efflux pumps that extrude the drug from the cytoplasm.²⁶⁷ The molecular target of the oxazolidinones is domain V of the 23S rRNA of the 50S bacterial ribosomal subunit. Binding to this domain results in the inhibition of the initial steps of translation.⁴⁶¹ Although there is some overlap with the binding sites of other antibiotics whose activity is directed against the ribosome,²⁶⁷ linezolid's binding site is unique to the oxazolidinones.

Resistance to linezolid in vivo has been an uncommon occurrence. Regional, national, and international surveys conducted during the 2010s, the second decade of the drug's licensure, identified remarkably few linezolid-resistant organisms among staphylococci, despite the widespread use of the agent. In most surveys, more than 98% of *S. aureus* (including MRSA) and coagulase-negative staphylococci were linezolid susceptible.^{76,205,241,297} Resistance in enterococci occurs more frequently; in some regions, susceptibility of vancomycin-resistant enterococci has fallen below 90%.⁴³⁷ The few endemic linezolid-resistant clinical isolates usually have been encountered after prolonged exposure to drug.^{32,145} Intrahospital and regional epidemics of linezolid-resistant coagulase-negative staphylococci and vancomycin-resistant enterococci also have been reported; resistance resulted from clonal spread of resistant organisms.^{213,327,329,330,539}

Four principal mechanisms of linezolid resistance have been defined. Most linezolid-resistant organisms possess a mutation in the gene encoding domain V of the 23S rRNA.^{267,296,382} Most bacteria have multiple copies of this gene. The degree of resistance depends on the gene dose, and the MIC of linezolid usually remains in the susceptible range after a single mutation occurs but increases incrementally as each allele is affected.²⁹⁶ In other linezolid-resistant organisms, the resistant phenotype is conferred through mutations of the ribosomal proteins L3 and L4.²⁶⁷

Through a third mechanism, ribosomal binding of linezolid is inhibited by methylation of the rRNA; this mechanism is mediated through the plasmid-borne enzyme Cfr methylase.^{20,50,58,267,382} Methylation results in cross-resistance to clindamycin and the streptogramin A antibiotics.²⁶⁷ In some instances, Cfr-bearing plasmids include several other antibiotic-resistance determinants.¹⁴⁰ Fourth, a transmissible ABC transporter gene (*optrA*) that can confer linezolid resistance was identified in enterococci in China in the mid-2010s.^{51,502} This efflux gene also extrudes phenicol antibiotics, which have been used in animal husbandry for years. Organisms carrying the *optrA* gene were isolated before the introduction of linezolid in China, presumably arising in the phenicol-exposed food chain.⁵⁰²

Daptomycin. Daptomycin, a fermentation product of *Streptomyces roseoporus*, is a unique antimicrobial with activity against a full range of gram-positive bacteria. The compound is a cationic cyclic lipopeptide that interacts with the cell membrane in a manner similar to related cationic peptides that constitute part of the natural human host defense mechanisms against microbes. In the presence of calcium, this event disrupts the transmembrane electrical potential with a secondary interruption of ATP and macromolecular synthesis.⁴⁴⁸ As with linezolid, laboratory surveys of large numbers of gram-positive clinical isolates

from many areas of the world indicate that daptomycin resistance is rare.^{76,410,437,481} Soon after daptomycin was introduced in the early 2000s, however, several cases were reported documenting the emergence of *S. aureus* and enterococci with reduced susceptibility to daptomycin during prolonged therapy.^{7,221,276,280} In these cases, the infection emanated from a bony or endovascular focus into which penetration of the drug might have been limited.

Daptomycin resistance has been linked to mutations in multiple genes that regulate the composition and integrity of the bacterial cell membrane.^{124,305} The mutations implicated in daptomycin resistance are different in *S. aureus* and enterococci, but in sum, they result in alterations in the phospholipid content of the bacterial cell surface, changing its charge and thereby decreasing the affinity of the drug to its target.^{7,221,305,407,477} In *S. aureus*, ultrastructural analysis of daptomycin-resistant isolates reveals a thickened envelope, and several reports have correlated vancomycin-intermediate resistance in *S. aureus* and reduced susceptibility to daptomycin.^{7,75,244} At the molecular level, an accumulation of gain-in-function mutations results in coincident reduction in susceptibility to both drugs. Chief among these are single-point mutations in the regulatory apparatus for the staphylococcal multiple protein resistance factor gene (*mprF*)⁵²¹, which results in an enhanced bacterial surface positive charge.^{18,61}

Ceftaroline. The fifth-generation cephalosporin ceftaroline was introduced into clinical practice in the latter part of the 2000s. Unlike all prior cephalosporins, ceftaroline exhibits a high affinity for the penicillin-binding protein PBP2A responsible for conferring methicillin resistance in staphylococci,⁴²⁰ rendering the drug active against MRSA. It also has activity against multidrug-resistant pneumococci and against staphylococci with intermediate resistance to vancomycin and reduced susceptibility to linezolid and daptomycin.⁴²⁰

Several surveys testing ceftaroline against a wide range of staphylococcal and pneumococcal clinical isolates in the first decade of the 2000s demonstrated almost uniform in vitro activity,^{114,119} but continued surveillance into the next decade indicated a growing proportion of nonsusceptible isolates among MRSA, ranging between 5% and 10%, from a wide variety of lineages and geographic regions.^{113,215,409,411} Resistance rates approaching 50% were documented in Southeast Asia.²³

The principal mechanism of resistance in MRSA strains is mutation of PBP2A.²⁹⁸ Mutation in the ceftaroline binding pocket of the transpeptidase region of this penicillin-binding protein renders the organism highly resistant,^{157,222,237,266} whereas mutations in other domains of PBP2A and alterations of other PBPs result in milder elevations of MIC.^{4,237} Some analyses of archived MRSA have documented ceftaroline resistance in isolates identified in the 1990s, well before the fifth-generation cephalosporins were introduced into clinical practice.²²²

Quinolones

Clinical Relevance

The quinolone family of antibiotics possesses activity against a broad variety of microorganisms. The safety profile for children of the more recently developed quinolones (i.e., fluoroquinolones) is similar to that recorded for adults.^{132,198} This class of antibiotics has been effectively employed in selected children with serious infections caused by bacteria resistant to alternative agents. The following sections discuss clinical circumstances in which quinolone resistance is relevant to pediatric infections.

Bacterial enteritis. Antibiotic therapy, including treatment with quinolones, for bacterial enteritis usually is not indicated.⁵¹⁴ That said, with the exception of *Campylobacter*, most agents that cause bacterial enteritis have remained susceptible to the quinolones by in vitro testing, although epidemic strains of *Shigella* and *Salmonella* expressing quinolone resistance have been identified worldwide.^{127,139,464} *Salmonella typhimurium* DT104, which spread rapidly throughout Europe and the United States in the late 1990s, is resistant to nalidixic acid, but most isolates (except for some identified in the United Kingdom) are susceptible to the newer fluoroquinolones.^{139,161,306} Similarly, surveys of other non-*typhi* *Salmonella* conducted in the early 2000s indicated that few were ciprofloxacin resistant, although as many as one fifth of the strains had reduced susceptibility to the drug.^{278,452}

In contrast to resistance among other enteritis-associated bacteria, high-level quinolone resistance among *Campylobacter* isolates from

many parts of the world has become prominent.^{169,362} *Campylobacter* can acquire quinolone resistance shortly after exposure to the antibiotic, and clinical relapse with quinolone-resistant organisms after therapy for *Campylobacter* enteritis is relatively common.³⁶²

The introduction of quinolones into poultry feed for animals bred for food has exacerbated the spread of *Campylobacter* resistance in humans.³²⁰ In chickens obtained from several different supermarkets in Minnesota in the mid-1990s, almost 90% of samples were culture positive for *Campylobacter*, and approximately 20% of these samples were resistant to ciprofloxacin.⁴⁴¹ These circumstances prompted a US Food and Drug Administration (FDA) ruling withdrawing the use of quinolones in poultry in 2005. It is likely, however, that quinolone-resistant *Campylobacter* has found a stable ecologic niche in animals and humans and will continue to be encountered despite this intervention.³²⁰

Unlike most other bacteria, *Campylobacter* becomes highly resistant to the quinolones after a single mutation.^{136,501} Most quinolone-resistant clinical isolates demonstrate MICs of 32 µg/mL or more, much higher than the conventional cutoff for defining quinolone resistance.

Urinary tract infections. Quinolone resistance in enteric gram-negative rods, particularly among uropathogens, was an uncommon occurrence in North America until the emergence of the multidrug-resistant extraintestinal pathogenic *E. coli* (ExPEC) clonal strains in the late 1990s and 2000s, predominately affecting health care-associated infections in adult patients. In a report on antimicrobial-resistant pathogens in device-related infections by the US National Healthcare Safety Network (NHSN), the percentage of pathogenic fluoroquinolone-resistant (FQR) *E. coli* associated with catheter-associated urinary tract infections (CAUTIs) was 24.8% in 2006 through 2007.¹⁶⁵ This percentage increased to 31.2% in the 2009-2010 NHSN report.⁴³⁶

Increases also have been reported in community-acquired UTIs, particularly in association with the pandemic ST131 *E. coli* strain, which encodes ESBIs and plasmid-mediated resistance to fluoroquinolones.³⁵⁹ In a national study of third-generation cephalosporin-resistant (G3CR) and ESBP-producing pediatric Enterobacteriaceae isolates, most of which were recovered from the urinary tract, coresistance to quinolone antibiotics was demonstrated in 32.8% and 54.3% of isolates, respectively.²⁶³ The U.S. data are consistent with trends in quinolone-resistant gram-negative urinary tract pathogens worldwide. In the 2009-10 global surveillance study for Monitoring Antimicrobial Resistance Trends (SMART), of 1116 FQR gram-negative UTI pathogens, the regional rates of FQR were 23.5% in North America, 25.5% in the South Pacific, 29.4% in Europe, 33.2% in Asia, and 38.7% in Latin America.³¹

Cephalosporin antibiotics remain effective overall in pediatric uncomplicated UTIs, and the consensus is that routine use of quinolone will needlessly promote quinolone resistance to an even greater degree without clinical benefit.^{118,146,175} The current recommendation from the American Academy of Pediatrics Committee of Infectious Diseases is to reserve quinolone use to cases of complicated UTI and pyelonephritis for which typical agents are not appropriate based on susceptibility data, allergy, or history of adverse events.³⁶

Community-acquired respiratory tract infections. The applicability of quinolones to respiratory tract infections has been shadowed by the marginal activity of the first modern quinolones—ciprofloxacin, ofloxacin, and norfloxacin—against *S. pneumoniae*. MICs of these antibiotics against most clinical isolates of *S. pneumoniae* average 1 to 2 µg/mL, concentrations that are close to those achievable in bronchial secretions.³⁶⁴ Several reports of clinical treatment failures were reported when ciprofloxacin was administered for pneumococcal disease in the respiratory tract.^{231,246} Even when *S. pneumoniae* was not the intended target of therapy, the widespread use of the early quinolone agents in treating community-acquired infections during the 1990s resulted in the inadvertent exposure of respiratory tract colonizers, including *S. pneumoniae*, to these agents. This was associated with a gradual increase in the MICs of community-acquired *S. pneumoniae* isolates to ciprofloxacin.^{63,203,415}

Most of the recently introduced fluoroquinolones are substantially more potent against *S. pneumoniae* than is ciprofloxacin, and they express MICs that are easily achieved in the respiratory tract. Susceptibility usually is maintained, even in isolates resistant to the older quinolone

agents.^{206,364} However, MICs against the newer quinolones roughly correlate with those expressed against ciprofloxacin. Consequently, clinically relevant resistance also has begun to emerge against these newer agents, particularly levofloxacin.^{2,91,369,400} Susceptibility of other respiratory tract pathogens, including *H. influenzae*, *M. catarrhalis*, and the bacterial agents causing atypical pneumonias, remains very good to all the fluoroquinolones, although exceptions, particularly in *Haemophilus* spp., have been reported (http://cddep.org/sites/default/files/swa_2015_final.pdf).

Beyond issues of promoting resistance, in 2016, the FDA advised against the use of fluoroquinolones for uncomplicated infections such as routine respiratory tract disease, stating that the serious adverse effects of quinolones outweigh their benefits. (<http://fda.gov/Drugs/DrugSafety/ucm500143.htm>). For children, fluoroquinolone antibiotics are recommended only as alternative therapy for acute otitis media, sinusitis, and lower respiratory tract infections.^{35,36,495}

Nosocomial infections. The quinolones traditionally have been mainstays of treatment for nosocomial infections in adult patients with severe illness. During the late 1990s and early 2000s, however, quinolone resistance in nosocomial gram-negative pathogens increased in many areas of the world among Enterobacteriaceae and non-lactose fermenters.^{125,207,216,322} In several instances, quinolone resistance in gram-negative bacilli increased more rapidly than any other resistance phenotype.^{125,207} Many of these hospital-acquired pathogens coexpress ESBLs and other resistance determinants.

Mechanisms of Resistance

The two principal molecular targets of the quinolone antibiotics are the topoisomerases DNA gyrase and topoisomerase IV. These enzymes mediate the three-dimensional topologic configuration of the bacterial duplex DNA ring during cell division and transcription and allow the repair and replication of nucleic acids and the separation of daughter chromosomes in the cramped intracellular environment.^{158,170} Several reactions are mediated by these two bacterial DNA topoisomerases, including negative supercoiling and catenation.^{171,459} In DNA gyrase and topoisomerase IV, the enzymes are heterotetramers with two subunits; gyrase is constructed as GyrA₂B₂ and topoisomerase IV as ParC₂E₂.^{173,171,459} The GyrA subunit is homologous to ParC, as the GyrB subunit is homologous to the ParE subunit.⁵⁰⁰ Quinolones bind reversibly to the GyrA and ParC subunit of the DNA gyrase and topoisomerase IV-DNA-ATP complexes near the active site tyrosine and prevent further progress of the enzyme along the nucleic acid.¹⁷¹ Bacterial cell death is enhanced by the release of toxic DNA ends from the quinolone-topoisomerase complexes.^{158,172}

Quinolone resistance is conferred through several molecular mechanisms (described later). Multiple mutations commonly occur in the same isolate, each one resulting in a higher MIC.

Mutations of topoisomerase. Most organisms resistant to the fluoroquinolones demonstrate one or more mutations in DNA gyrase or topoisomerase IV, or both. Resistance to quinolones among gram-negative bacteria usually is mediated through mutations in DNA gyrase, whereas resistance in gram-positive organisms is primarily the result of alterations of topoisomerase IV.^{158,343} However, this pattern varies from organism to organism (e.g., the primary target in *S. pneumoniae* appears to be DNA gyrase) and from quinolone to quinolone.^{158,172}

The mutations are clustered in the amino-terminal domains of GyrA or ParC, which reside near the active-site tyrosines of the enzymes. These domains are called the *quinolone-resistance determining region* (QRDR).^{173,522,523} Hybrid DNA gyrase molecules composed of the A subunit from a resistant bacterial strain and the B subunit from a susceptible isolate exhibit quinolone resistance.⁵² Within the QRDR, most mutations involve the substitution of a serine for a bulkier, nonpolar amino acid at a single, specific site. This mutation, first identified in *E. coli*,^{490,522} has since been documented in a variety of organisms, and it reduces quinolone affinity for the target enzyme-DNA complex.^{187,232,307,387} Other amino acid substitutions near this site also have been described, with multiple-site mutations resulting in increased quinolone resistance compared with a single mutation alone.⁴⁹⁰

Mutations of the GyrB and ParE subunits, which result in a quinolone-resistant phenotype, also have been identified in quinolone-resistant

clinical isolates but remain less common than mutations in GyrA and ParC. Mutations affecting the GyrB subunit usually result in lower levels of resistance than those seen with GyrA.⁵²³ As with GyrA mutations, those affecting GyrB preferentially localize to specific amino acids.⁵²³

Altered outer-membrane porin. Another mechanism of quinolone resistance involves decreased entry of antibiotic into the cell due to alterations in porin composition, a mutation that usually results in only moderate drug resistance and that affects individual quinolones differentially, depending on their hydrophilicity.⁴¹⁸ Attention has focused on alterations in outer-membrane protein F (OmpF).^{174,534} This mutation, identified principally in *E. coli*, frequently is associated with resistance to other classes of antibiotics, including chloramphenicol, tetracycline, and some of the β -lactams. The diminished expression of OmpF in these resistant isolates does not appear to result from mutations in the corresponding structural gene or its regulatory sequences. Rather, the decreased expression of this outer-membrane protein is mediated through the enhanced expression of the gene *micF*, which transcribes an antisense RNA complementary to the 5' end of the *ompF* message,⁶ thereby destabilizing its binding to the ribosome. Occasional mutants involving additional strains of Enterobacteriaceae have demonstrated other alterations in outer-membrane porin composition.⁵²

Efflux. Quinolone-resistant species can also mediate their resistance through increased drug efflux.^{250,251} Bacterial and eukaryotic cells normally encode several efflux pumps that provide protection from a range of potential exogenous toxins.³⁵² The overexpression of an efflux pump resulting from the mutation of a controlling sequence accounts for reduced susceptibility to quinolones in many clinical isolates.^{191,279} In gram-positive bacteria, the largest contributors of quinolone efflux transporters are members of the major facilitator superfamily (MFS); in gram-negative bacteria, most quinolone-related efflux pumps are derived from the resistance-nodulation-division (RND) superfamily.²⁵³

Individual efflux pumps select substrates based on their physical chemical properties (e.g., hydrophobicity, net charge), rather than their gross structural similarities. The various quinolone compounds, which vary in these properties, can be differentially susceptible to organisms expressing these pumps.³⁵²

The genes encoding the Nor MFS pumps in *S. aureus*, called *norA*, *norB*, and *norC*,^{173,524} have been cloned, sequenced, and comprehensively analyzed. Transformation of susceptible bacteria with the putative gene results in a resistant phenotype, which can be abolished by the addition of inhibitors of energy-dependent cellular pumps.⁵²⁴ NorA can transport only hydrophilic quinolones (e.g., norfloxacin, ciprofloxacin); intracellular accumulation of the hydrophobic drugs sparfloxacin and moxifloxacin, for example, are unaffected. NorB and NorC have broad substrate profiles and can transport hydrophilic and hydrophobic quinolones.^{252,479,480,484,526}

Several other MFS efflux transporters affect quinolone resistance in *S. aureus*.¹⁷³ Additional transporter families such as the ATP-binding cassette (ABC) family and the multiple antibiotic and toxin extrusion (MATE) family can confer quinolone resistance.¹⁷³ A range of additional genes encoding efflux pumps capable of producing quinolone resistance has been identified in other species, such as *prmA* in *S. pneumoniae*,³⁶³ *acrAB-TolC* complex in *E. coli*,²⁷⁴ and the *mexAmexB-oprM* complex in *P. aeruginosa*.²⁸¹ This third complex gene encodes components that transport the drug through the cell wall and across the periplasmic space as well as an outer-membrane protein.³⁵² Most pumps can extrude a wide variety of exogenous substances, such as detergents, dyes, and other antibiotics, from the bacterial cytoplasm.¹⁹¹ Therefore reduced susceptibility to quinolones may be selected by exposures unrelated to the quinolones themselves.

Plasmid-mediated quinolone resistance. The first decade of the 2000s witnessed the rapid emergence of transmissible plasmid-mediated quinolone resistance (PMQR). All previously defined mechanisms of quinolone resistance were chromosomal. Organisms exhibiting the transmissible mechanism have been identified in several countries worldwide.⁴⁰² The three main mechanisms of PMQR are production of proteins that protect DNA gyrase and topoisomerase IV from inhibition by quinolones; acetylation of quinolones by variants of aminoglycoside acetyl transferases; and efflux pumps.

Qnr proteins. The first PMQR products discovered, called *Qnr* proteins, are a group of molecules that bind to topoisomerase and protect

it from the inhibitory effects of the quinolones.^{325,402} Although all the Qnr molecules described belong to the pentapeptide-repeat family of proteins, a finding suggesting similar three-dimensional conformations, distinct families of Qnr proteins with largely nonhomologous amino acid sequences have been characterized.^{325,402} These families have been named QnrA, QnrB, QnrC, QnrD, and QnrS, with subtypes identified within each.

Qnr homologues are encoded on the chromosomes of gram-positive and gram-negative bacteria, suggesting distinct and widely different origins of Qnr genes. The variety of plasmid and integron structures carrying Qnr proteins and the multiplicity of sequences of the proteins themselves support the notion that Qnr-mediated resistance arose through many independent molecular events before the introduction of quinolones in geographically distinct regions of the world.¹⁹⁵ The plasmids encoding the Qnr proteins have been found in multiple species belonging to the Enterobacteriaceae, but they are infrequently identified in nonenteric bacteria such as *Pseudomonas* and *Acinetobacter*.^{402,476}

AAC(6′)-Ib-cr gene. Qnr plasmids frequently carry other antibiotic-resistance genes, most notably those encoding ESBLs and the aminoglycoside-modifying gene *aac(6′)-Ib-cr*, which also can acetylate selected quinolones.^{195,402} The *aac(6′)-Ib-cr* variant requires two unique amino acid substitutions (i.e., Asp179Tyr and Trp102Arg) for the acetylation of quinolones. Plasmids harboring the *aac(6′)-Ib-cr* gene are often located on an integron that is associated with other plasmid-mediated quinolone-resistance genes and additional antibiotic-resistance genes. The plasmids can be found, for example, in the multidrug-resistant epidemic *E. coli* ST131 strain. The *aac(6′)-Ib-cr* genes have been recovered from multiple members of the Enterobacteriaceae family and have been reported in *P. aeruginosa*.^{173,195,359,402}

OqxAB and QepA efflux pumps. OqxABs are efflux pumps in the RND family. Genes for OqxAB are frequently found on the chromosomes of gram-negative organisms (e.g., *K. pneumoniae*, *Enterobacter* spp.). Plasmid-mediated variants were originally described in 2003 in association with a conjugative plasmid conferring resistance to a growth-enhancing food additive in pigs (i.e., olaquinox).⁴⁴⁶ This was later discovered to be a multidrug efflux pump, conferring resistance to quinolones, trimethoprim, nitrofurantoin, and chloramphenicol.^{155,166} PMQR due to OqxAB variants is expressed at higher levels than the chromosomal counterpart. In countries where olaquinox is used in agriculture, such as China, stool colonization with OqxAB harboring *E. coli* in farm animals (40%) and farm workers (30%) is common.^{155,166,537,538}

QepAs are efflux pumps in the MFS family that increase resistance to hydrophilic quinolones. The QepA variants, originally reported in 2007 in *E. coli*, have been found worldwide. They are most commonly located on plasmids in association with genes encoding the aminoglycoside ribosomal methylase (*rmtB*). QepA expression varies, accounting for differences in the levels of quinolone resistance in QepA-harboring isolates.^{150,195,357,520,538}

Polymyxins

Clinical Significance

The polymyxin antibiotics are represented by two agents: polymyxin B and polymyxin E; the latter is more commonly known as colistin. The drugs were introduced in the 1950s for parenteral therapy against a wide variety of gram-negative pathogens. Because of the high incidence of nephrotoxicity and, to a lesser extent, neurotoxicity, intravenous use of these drugs was relegated to a minor role when alternative agents became available.

By the early years of the new millennium, a growing number of hospital-associated organisms worldwide had become simultaneously resistant to multiple classes of parenteral antibiotics, including all available β -lactams, aminoglycosides, and fluoroquinolones, severely limiting therapeutic options during a period when new drug development against gram-negative bacteria was almost at a standstill. These circumstances led to a resurgence of intravenous colistin use.^{111,249} The rejuvenation of parenteral colistin as an antibiotic of last resort was met with the sobering recognition that optimal dosing regimens in adults had never been established and the subsequent documentation that conventional dosing developed decades before could lead to subtherapeutic

concentrations of the drug at the infected site.³¹⁷ Pharmacokinetics and pharmacodynamics in children were even less defined.¹⁷⁶

With broader use of intravenous colistin, there has been a growing recognition of resistance to the drug.³⁸³ When expressed in multidrug-resistant, carbapenemase-expressing organisms, this has sometimes resulted in an infection for which there are few or no therapeutic options.⁴⁸⁶ The species most frequently associated with colistin resistance include *P. aeruginosa*, *A. baumannii*, and *K. pneumoniae*; all are virulent pathogens whose primary targets are fragile, critically ill people.

The frequency of colistin resistance is poorly defined because accurate susceptibility testing to colistin requires the time-consuming broth microdilution technique⁷⁷ and usually is reserved for the subset of clinical isolates expressing multiple-resistance phenotypes. A partial picture of the frequency of colistin resistance was presented in a survey of 19,719 international Enterobacteriaceae isolates published in 2015³⁴: 1.6% were colistin resistant, but the incidence increased to 12% in carbapenem-resistant organisms, mostly in *K. pneumoniae*. The incidence of colistin resistance among all gram-negative species likely will increase significantly within a short period.

Until recently, colistin resistance was exclusively expressed chromosomally and was spread through clonal expansion and person-to-person transmission of selected strains. In the 2010s, outbreaks in hospitals and in long-term care facilities caused by one or a small number of genetically related organisms were described,^{135,331} sometimes involving interinstitutional spread. In early 2016, a plasmid-borne transmissible form of colistin resistance was identified in *E. coli* in China.²⁵⁹ This alarming finding generated multiple international surveys, which revealed that organisms bearing the resistance plasmid had already spread throughout the world.^{353,373,426,493}

Agricultural use of polymyxins has been ongoing for decades. A high incidence of organisms expressing transmissible colistin resistance have been found in farm animals, particularly pigs and poultry, and in meats coming to market for human consumption, strongly suggesting a zoonotic origin of this resistance determinant.^{373,426}

Mechanisms of Resistance

The polymyxins are amphipathic molecules that initially bind to the lipid A component of lipopolysaccharide. The antibiotic then mediates fusion with the cytoplasmic membrane underneath, resulting in cell surface disruption, osmotic imbalances, and death.²¹⁹ Chromosome-encoded resistance results from the synthesis of normally repressed products (e.g., 4-amino-4-deoxy-L-arabinose or phosphoethanolamine, depending on the species) that modify the lipopolysaccharide, reducing its affinity for the polymyxin.²⁶

Synthesis of these molecules is regulated by a two-component system composed of a cell surface kinase and the resistance-determinant gene itself (i.e., PmrA/PmrB or PhoP/PhoQ). Phenotypic resistance may result from mutations of the kinase or the resistance gene.²¹⁹ Disruption of an additional negative regulator, the *mgrB* locus in *K. pneumoniae*,^{53,338} also results in the resistant phenotype.

Transmissible resistance is mediated by the *mcr-1* gene that has been identified in *E. coli* on a particularly promiscuous conjugative plasmid.²⁵⁹ The MCR-1 product is a phosphoethanolamine transferase enzyme that mediates the addition of that molecule to lipid A. Sequence analysis suggests that this enzyme initially was derived from a gene on the chromosome of a bacterium that naturally produces polymyxin, which then became incorporated onto a plasmid and transferred to *E. coli*.²⁵⁹

Chloramphenicol

Clinical Relevance

In industrialized nations, chloramphenicol has been supplanted by other agents with similar or improved antibacterial potency and less toxicity. However, the antibiotic remains a staple for pediatric bacteremia and meningitis in the developing world because of its broad antibacterial activity, low cost, favorable achievable serum concentrations after oral or intramuscular administration, and excellent penetration across the blood-brain barrier.

The incidence of resistance to chloramphenicol among the principal organisms causing bacteremia and meningitis in children—*H. influenzae*, *S. pneumoniae*, *N. meningitidis*, and *Salmonella*—varies greatly by

geographic location. Between the late 1980s and the early 2000s, surveys of type b and non-type b *H. influenzae* were completed in several areas of the world. In vitro resistance to chloramphenicol was between 0% of isolates (i.e., Central African Republic and various locations in South America) and more than 50% (i.e., India and Kenya).^{200,225,336,406,414,505} Studies in 2001 and 2003 of *H. influenzae* isolates in Canada and the United States, where infection by these organisms is almost always treated with an alternative agent, indicated chloramphenicol resistance in less than 0.5% of tested bacteria.^{167,535}

International surveys completed in the middle to late 1990s that measured in vitro susceptibility of *S. pneumoniae* to chloramphenicol indicated resistance exceeding 10% to 20% in many areas of the world.^{189,247,336,406} Chloramphenicol resistance was identified in approximately 10% of European isolates of *S. pneumoniae* and in 5% of isolates in the United States and Canada.¹⁶⁷ Resistance to chloramphenicol is seen more commonly and is of a higher grade in penicillin-resistant pneumococci than in isolates that are penicillin susceptible.¹⁶⁷ Even in penicillin-intermediate or penicillin-resistant strains that retain in vitro susceptibility to chloramphenicol, the clinical response to chloramphenicol in cases of meningitis is poor. Some investigators have suggested that the bacteria express high minimal bactericidal concentrations to chloramphenicol; as a result, concentrations of drug achieved in the cerebrospinal fluid with routine dosing are lower than those required for good outcomes in central nervous system infections.¹²⁶

Chloramphenicol retains excellent activity against most strains of *N. meningitidis*. However, investigators described meningococcal strains from Vietnam, Paris, and Australia that possessed high-level resistance to the drug.^{128,435} Chloramphenicol resistance in *Salmonella* spp., a fourth group of organisms that causes disseminated disease and meningitis in pediatric patients, varies geographically. Resistance with a prevalence exceeding 50% usually is detected in developing countries,²¹⁴ where chloramphenicol has been a readily available oral agent for typhoidal and nontyphoidal *Salmonella* infections for decades. In most *Salmonella* isolates, chloramphenicol resistance occurs coincident with resistance to many other antibiotics, particularly ampicillin, sulfonamides, tetracycline, and some of the older aminoglycosides. Chloramphenicol resistance has become increasingly common in industrialized nations.^{72,444,504} In the United States, the strain *Salmonella typhimurium* DT104, which similarly coexpresses resistance to several classes of antibiotics, including chloramphenicol, has become a widespread health hazard.^{1,491}

Mechanisms of Resistance

The antibacterial activity of chloramphenicol is conferred by its interference with the peptidyl transferase region of the 50S prokaryotic ribosome. The principal mechanism of resistance is expression of the modifying enzyme chloramphenicol acetyltransferase (CAT), which catalyzes the acetylation of the C3-hydroxy group of the drug and prevents its binding to the bacterial ribosome.⁴³¹

CATs represent a family of enzymes. Many CATs share chemical properties and structural homologies, especially around the active site.⁴³¹ CATs frequently reside on plasmids or transposons that carry other antibiotic-resistance determinants.⁴⁹⁴ In *Salmonella*, the chloramphenicol-resistance gene frequently is encoded on a class 1 integron incorporated in the *Salmonella* genomic island 1 (SGI1), which includes multiple antibiotic-resistance cassettes.^{102,311} SGI1 is transmissible and has been identified in many different *Salmonella* serovars.

Alternative mechanisms of resistance to chloramphenicol have been identified in certain gram-negative species. In most of these organisms, resistance is linked to decreased intracellular accumulation of drug. In chloramphenicol-resistant *Pseudomonas*, this phenomenon has been associated with the overproduction of an approximately 50-kD outer-membrane protein,²⁵¹ which in the past led to the speculation that entry of drug into the bacterium was diminished by an abnormal porin. However, cell membrane proteins of this size have also been identified as components of a complex efflux apparatus that include the pump and proteins that channel the extruded substance across the periplasmic space and through the outer membrane.³⁵² More direct evidence of multidrug-resistant efflux pumps has been identified in chloramphenicol-resistant *E. coli*,¹⁵⁵ *Pseudomonas*,²⁵¹ *Stenotrophomonas*,³⁵⁶ and *Salmonella*.^{27,60,365} Usually, these

pumps result in coresistance to multiple antimicrobial agents, including tetracycline, sulfonamide, aminoglycosides, quinolones, and selected detergents.

The Pharmacokinetic-Pharmacodynamic Interface: Determinants of Antiinfective Drug Action and Efficacy in Pediatrics

235

Jennifer L. Goldman • Susan M. Abdel-Rahman • Gregory L. Kearns

The *pharmacokinetic-pharmacodynamic interface* reflects an association between two determinants of drug effect—delivery of drug to the site of action and the intrinsic activity of a drug to alter cellular function after it reaches that site. The conjoint consideration of drug disposition (i.e., pharmacokinetics) and drug action (i.e., pharmacodynamics) is of critical importance in the selection and evaluation of any antiinfective drug regimen. In much of the contemporary clinical pharmacology and therapeutics literature, *kinetics* generally is associated with a description of the rate processes associated with drug absorption, distribution, metabolism, and excretion (ADME). Although accurate in its definition concerning the movement of drugs into and out of the body, kinetics as a determinant of drug effect must be viewed in a much broader context, specifically, the sojourn and fate of a drug molecule in both the extracellular and intracellular milieus. Although understanding this facet of drug behavior admittedly is difficult because of a relative inability in the clinical context to track the intracellular fate of a drug in humans, achieving a high degree of control over antiinfective therapy by the application of well-characterized and understood kinetic principles is quite possible.

The focus of this chapter is on the pharmacologic considerations necessary for the prudent use of antiinfective agents in pediatric patients,

specifically, the pharmacokinetic and pharmacodynamic principles that, if embraced, can be the key to optimizing drug treatment and maximizing therapeutic efficacy and safety. The pediatric patient presents a particular challenge to the clinician. Although pediatric practitioners recognize that “children are not just miniature adults,” more difficult to appreciate are the dramatic changes associated with normal human growth and development that can, and many times do, exert a profound influence on drug disposition, drug action, and, ultimately, therapeutic outcome of antiinfectives.¹¹⁹ Failure to compensate for developmental differences in pharmacokinetics in the context of therapeutic drug use in pediatrics can increase the risk for occurrence of adverse drug effects associated with either overdose (i.e., drug toxicity) or underdose (i.e., lack of efficacy).^{82,119}

In the following sections of this chapter are basic principles required to understand the pharmacokinetic-pharmacodynamic interface in pediatrics, namely, general principles in pharmacokinetics, the impact of development on drug disposition, the pharmacokinetic determinants of drug action, and methods to facilitate clinical integration of the pharmacokinetic and pharmacodynamic properties necessary to optimize antiinfective therapy.

PHARMACOKINETIC DETERMINANTS OF EXPOSURE

Implicit in the production of any pharmacologic effect is the association of a drug molecule with one or more receptors and the subsequent propagation of intracellular events that ultimately translate into drug action. In general terms, successful drug-receptor interactions are characterized by three principles: (1) *avidity*, the ability of a drug to combine with a receptor; (2) *affinity*, the physical combination of a drug with a receptor, and (3) *intrinsic activity*, the ability of the drug-receptor combination to generate one or more “impulses” or “signals” capable of activating biologic effector systems. The primary determinants of both avidity and affinity reside with the maintenance of structural specificity of both the drug and receptor to ensure that an association with one or more physicochemically distinct, active sites can occur. Simply stated, a drug molecule must fit into a receptor as a key fits into a lock before intrinsic activity becomes a possibility. The receptor or receptors thus will function in the role of cellular targets for drug molecules when an effective combination is required for drug effect and, ultimately, therapeutic efficacy.

The onset and offset of drug action are determined not only by receptor-modulated intrinsic activity but also by receptor occupancy. In almost all instances, these events are both concentration and time dependent. Hence the disposition of a drug in the body (e.g., ADME) becomes the “driver” for its pharmacodynamics. This action is particularly true for anti-infective drugs when the therapeutic target, the infecting organism, must be exposed to a sufficient concentration of pharmacologically active (i.e., free) drug for a period sufficient for drug binding to critical cellular elements (e.g., penicillin-binding proteins [PBPs], intracellular enzymes) to occur and for subsequent disruption of normal cellular function (e.g., inhibition of protein biosynthesis, inhibition of cell wall synthesis) to result in cellular demise. Thus the clinical determinants of drug efficacy (and safety), such as proper selection of both dose and dosing interval relative to the intrinsic sensitivity of the infecting pathogen or pathogens, and factors that determine delivery of the drug to the site or sites of infection embody the importance of pharmacokinetics in the selection and clinical use of anti-infective drugs.

BASIC TERMS

A complete discussion of pharmacokinetics is beyond the scope of this chapter because it would require a description of theory and a presentation of relatively sophisticated mathematical concepts. This information can be found in many excellent textbooks that provide both theoretical⁸¹ and conceptual^{119,194,242} presentations of pharmacokinetics and through Internet-based programmed instruction courses.²⁹ However, well within the scope of this chapter are a definition and glossary of pharmacokinetic terms sufficient to equip the reader with a conceptual, working knowledge of this pharmacotherapeutic tool. These definitions and concepts are presented as follows:

Absolute bioavailability (F) is the extent or fraction of drug absorbed after extravascular administration. It is determined by comparing the area under the plasma concentration versus time curve (AUC) after administration of an oral dose of a drug with the AUC after administration of an intravenous dose (e.g., $F = AUC_{PO} \times \text{dose}_{IV} / AUC_{IV} \times \text{dose}_{PO}$).

Relative bioavailability reflects the extent of drug absorbed from one dosage form given by an extravascular route of administration in comparison to a dose of a “reference” drug formulation administered by the same route. Generally, it reflects the relative extent of systemic availability (F) and is calculated by comparing the AUC of the test regimen relative to the reference formulation (e.g., $F = AUC_{\text{test}} \times \text{dose}_{\text{reference}} / AUC_{\text{reference}} \times \text{dose}_{\text{test}}$).

Absorption of drugs describes the process of drug uptake from a site of extravascular administration (e.g., oral, intramuscular, subcutaneous, intraperitoneal, intraosseous, intratracheal, intravaginal, intraurethral, sublingual, buccal, rectal, and dermal) into the systemic circulation. Drug absorption is conceptualized most accurately by considering both rate (e.g., absorption half-life, time to peak concentration) and extent (e.g., bioavailability), either of which can be influenced by biopharmaceutical (e.g., drug formulation), physicochemical (e.g., pH, solubility,

FIG. 235.1 Representative plasma concentration versus time curve. Illustrated are commonly referenced pharmacokinetic parameters. AUC, Area under the curve; C_{max} , maximal plasma concentration; k_e , elimination rate constant; and T_{max} , time to achieve maximal plasma concentration.

hydrophilicity and lipophilicity, protein binding, complexation characteristics with food or drugs), and physiologic (e.g., barrier integrity, motility, volume and pH of body fluids at the absorptive site, protein-binding capacity, degradation/biotransformation potential) factors.

Area under the curve (AUC) is, conceptually, a measure of both the extent of drug absorbed and its persistence in the body. It is the integral of drug blood levels over time from zero to either a predetermined postdose time point (i.e., $AUC_{0 \rightarrow \tau}$), the end of the dosing interval (i.e., $AUC_{0 \rightarrow \infty}$), or extrapolated to infinity (i.e., $AUC_{0 \rightarrow \infty}$) by using the apparent terminal elimination rate constant (similarly calculated from the observed plasma concentration versus time plot) (Fig. 235.1). AUC is therefore a pharmacokinetic parameter that is both time and concentration dependent.

Bioequivalence of a drug product is achieved if its extent and rate of absorption are not significantly different (i.e., within 80–125%) from those of a reference standard drug product when administered at the same molar dose. Bioequivalence is a pharmacokinetically determined parameter and does not entail a relative comparison of drug action or efficacy. Therefore, if a drug product (e.g., a generic drug) produces a rate and extent of absorption sufficiently similar to those of the reference formulation, the effect and toxicity profiles of the two drugs are assumed to be virtually identical.

Biopharmaceutics deals with the physical and chemical properties of the drug substance, the dosage form, and the body, as well as the biologic actions of a drug or drug product after administration. Biopharmaceutical considerations (e.g., rate and extent of the disintegration or dissolution of a dosage form, liberation of the active drug from a dosage form, solubility or binding of the drug at the site of absorption) can be rate limiting for drug absorption or bioavailability, or for both, and thus may limit the efficacy of drug therapy.

Clearance (Cl) of a drug is represented conceptually by the volume of blood from which a certain amount of unmetabolized drug is removed (i.e., cleared) per unit of time by any and all pathways capable of drug removal (e.g., renal, hepatic, biliary, pulmonary, breast milk, sweat). In pharmacokinetics, clearance generally is represented as total body (or plasma) clearance, renal clearance (Cl_{ren}), or nonrenal clearance (Cl_{nr}). Clearance is determined easily from knowledge of the drug dose, and AUC and can be calculated as follows:

$$Cl = \text{Dose (mg/kg)} / AUC \text{ (mg/L} \times \text{hour)}$$

where AUC can represent either the $AUC_{0 \rightarrow \tau}$ for single-dose administration, or the AUC from time zero to the end of the dosing interval at steady state (i.e., $AUC_{ss0 \rightarrow \tau}$). Calculation of renal clearance requires a complete, quantitative collection of urine (usually over the course of 24 hours) to determine the amount of drug excreted (A_e) unchanged. Nonrenal clearance generally is determined as the difference between

total body clearance and renal clearance. For drug administration by any extravascular route, calculation of clearance yields an apparent value (e.g., Cl/F) in that it must be corrected for the extent of the drug dose absorbed (i.e., the bioavailability) from the site of administration.

A compartment in pharmacokinetics represents a hypothetical space into and out of which drug partitions as a function of time. Compartment models are used in pharmacokinetics to characterize the relationship between drug dose and concentration as a function of time. The most simple of all pharmacokinetic models is a one-compartment open model in which the only applicable rate processes represent drug ingress and egress from a single theoretical or central space. A two-compartment model has been used to characterize the disposition of many anti-infective agents in both pediatric and adult subjects. This particular model is composed of a central compartment and a peripheral compartment, both of which represent the various fluids and tissues where a drug may reside. Although a compartment often may not correspond to a true physiologic space that can be characterized by a specific volume of biologic fluid, compartment models can be used to conceptualize both drug distribution between physiologic spaces and elimination from the body. In the two-compartment model, for example, the central compartment often is used to represent a drug resident within the intravascular space and the highly exchangeable extracellular fluid of tissues and organs that are well perfused, whereas the peripheral compartment represents drug distribution to intracellular fluid and tissues and organs that are less well perfused and, in some instances, the association of the drug (e.g., binding) to specific tissues or tissue components. In all instances, compartmental models oversimplify the true processes of ADME. However, they have been demonstrated repeatedly to be useful as a reliable means to model, and therefore predict, the relationship between drug dose and concentration in both plasma and tissue.

Disposition refers collectively to the processes of ADME, all of which occur simultaneously after administration of a drug, as opposed to being discrete pharmacologic events.

Dose-response curve is a graphic representation of the pharmacologic effect as a function of either the drug dose or the concentration of the drug. A log dose-response curve is often sigmoidal, whereas a cartesian concentration-effect curve is hyperbolic (Fig. 235.2). Theoretically, a drug concentration of zero indicates no drug effect (i.e., E_0). As a drug travels to and interacts with a receptor, the effect (E) increases in a concentration-dependent manner (i.e., $E = (E_{max} \cdot C)/(EC_{50} + C)$) to a point at which a maximal effect (E_{max}) is attained and above which higher drug concentrations fail to enhance the effect. A pharmacologically important term that can be derived easily from a concentration-effect curve is the EC_{50} , or the drug concentration for which the observed effect is 50% of the E_{max} .

Elimination half-life of a drug is the time necessary to reduce the drug concentration (in blood serum or plasma) by 50% after absorption is complete and distribution between body compartments has attained

FIG. 235.2 Representative nonlinear concentration (C) versus effect profile. E_{max} , Maximal effect; EC_{50} , drug concentration for which the observed effect is 50% of the maximal effect.

equilibrium. Loss of drug from the body, as represented by the elimination half-life, reflects elimination of the administered parent drug molecule (i.e., not its metabolites) by metabolism, urinary excretion, or other pathways capable of resulting in elimination of drug. Accordingly, many individuals use elimination half-life as a surrogate indicator of drug clearance. Such a determination should be made cautiously because this particular pharmacokinetic parameter is dependent on both clearance and the apparent volume of distribution (VD), as illustrated by the following equation: $t_{1/2} \text{ elimination} = [(0.693 \times VD)/Cl]$, where $t_{1/2}$ is half-life. Practically speaking, the elimination half-life is an important pharmacokinetic parameter because it can be used to determine the period of time required for a drug dosing regimen to produce steady-state plasma concentrations (e.g., $5 \times t_{1/2}$ elimination) and the dosing interval required to produce a desired excursion (i.e., peak and trough) in plasma drug concentrations.

Steady state reflects the level of drug accumulation in the blood and tissue after multiple doses when input (i.e., the amount of drug placed into the systemic circulation) and output (i.e., drug clearance) are at equilibrium. When drugs are given at fixed doses and dosing intervals, the steady-state concentrations fluctuate between a maximum (C_{max}) and minimum (C_{min}) within a given dose interval that are identical between doses, provided that the size of the dose, method of administration, dosing interval, or drug pharmacokinetics (or any combination of these parameters) does not change. For drugs that follow first-order pharmacokinetics, steady-state plasma concentrations for a given dosing regimen are attained over a period of time that corresponds to four to five times the elimination half-life. In general, the pharmacokinetics of a drug at steady state provides the most accurate correlate for examining drug effect.

First-pass effect describes a phenomenon whereby drugs may be metabolized or chemically degraded (or both) after extravascular administration before they reach the systemic circulation. Specific examples include biotransformation of selected drugs (e.g., cytochrome CYP3A4 substrates) in the enterocyte and nonenzymatic hydrolysis of an active drug (e.g., penicillin) in the lumen of the gastrointestinal tract (e.g., stomach, intestine, rectum). Drugs subject to a first-pass effect generally have a reduced rate or extent of relative bioavailability, or both, when compared with that achieved by parenteral administration.

Protein binding is the phenomenon that occurs when a drug (or metabolite) combines with plasma or extracellular or tissue proteins to form a drug-protein complex. In general, drug-protein binding usually is nonspecific and depends on the drug's affinity for the protein molecule (i.e., binding site), the number of protein-binding sites, and the drug and protein concentrations. With few exceptions, drugs that are bound to proteins are pharmacologically inactive and cannot be metabolized or excreted readily. The pharmacokinetic consequences of drug-protein binding can influence the drug dose versus the plasma concentration versus the effect relationship. For example, drugs with extensive tissue binding have apparent volumes of distribution that are far in excess of the total body water space and, in general, have relatively long elimination half-lives. Conditions in which intravascular proteins escape to extravascular sites (e.g., nephrotic syndrome, severe burns, ascites) can increase the apparent volume (and elimination half-life) of drugs that are extensively (i.e., $>70\%$) bound to albumin.

Volume of distribution (apparent volume of distribution) (VD) represents a hypothetical volume of body fluid that would be required to dissolve the total amount of a drug at the same concentration as that found in the blood and is illustrated by the following equation:

$$VD = \text{Dose}/C_p^0$$

where C_p^0 represents the highest attainable plasma concentration after the administration of a single dose. As a proportionality constant, the VD is a determinant of plasma drug concentrations attained after administration of a given drug dose. For drugs that are not distributed extensively or that bind with great affinity to proteins and tissues, the apparent VD may correspond dimensionally to physiologic or anatomic body spaces (e.g., $VD < 0.1$ L/kg approximates the intravascular space, 0.1 – 0.3 L/kg approximates the extracellular space, 0.6 – 0.7 L/kg approximates the total body water space), which, when altered by disease or

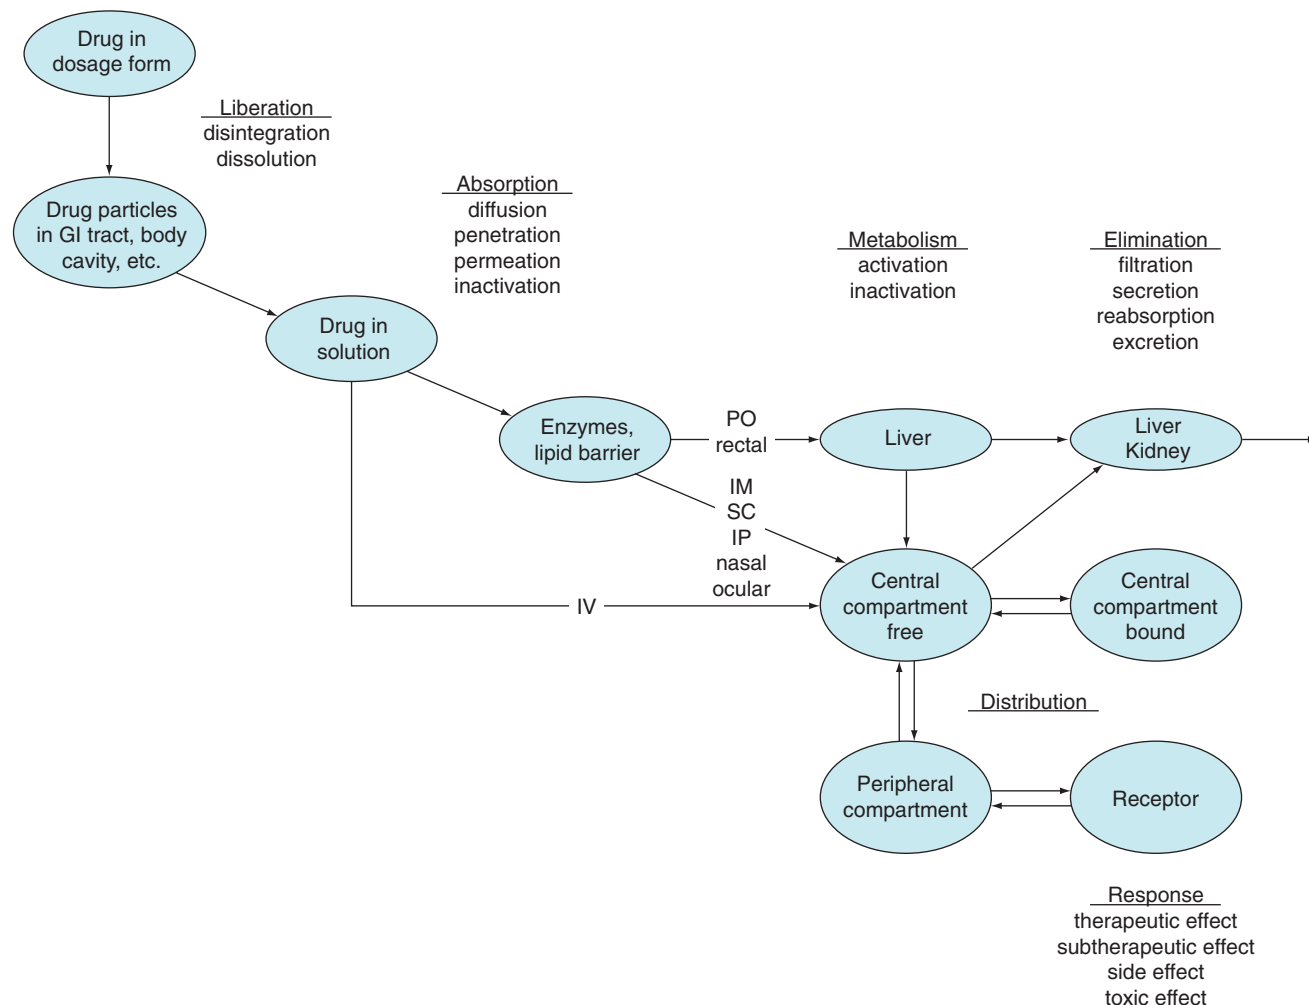

FIG. 235.3 Representation of the pharmacokinetic-pharmacodynamic interface. *GI*, Gastrointestinal; *IM*, intramuscular; *IP*, intraperitoneal; *PO*, oral; *SC*, subcutaneous.

development, or by both, will influence the apparent *VD* and thus the achievable concentration for a given drug.

A working knowledge of these pharmacokinetic definitions allows one to have an understanding of the relationships among drug dose, concentration, and effect. The use of knowledge related to the physicochemical and pharmacologic properties of a drug, the impact of isolated or concurrent variables on drug disposition, and predictors of pharmacodynamics or drug response enables the clinician to optimize the selection of agents and dosing regimens and thus individualize drug therapy. To accomplish this goal, it is imperative that the relationship between drug pharmacokinetics and pharmacodynamics not be compartmentalized, but rather, as illustrated in Fig. 235.3, be conceptualized as multifactorial, in which the determinants of drug concentration and effect are dynamic and change as a function of a disease state and drug therapy.

IMPACT OF ONTOGENY ON PHARMACOKINETICS

Development represents a continuum of biologic events that enable adaptation, somatic growth, neurobehavioral maturation, and, eventually, reproduction. The impact of development on the pharmacokinetics of a given drug is determined, to a great degree, by age-related changes in body composition and the acquisition of function in organs and organ systems that are important in determining drug metabolism and excretion. Although classifying pediatric patients on the basis of postnatal age (e.g., neonates, ≤ 1 month of age; infants, 1–24 months of age; children, 2–12 years of age; and adolescents, 12–18 years of age) often

is convenient for providing drug therapy, recognizing that the changes in physiology are not linearly related to age and may not correspond to these age-defined breakpoints is important. In fact, the most dramatic changes in drug disposition occur during the first 18 months of life, when the acquisition of organ function is most dynamic. Additionally, the pharmacokinetics of a given drug may be altered in pediatric patients as a result of intrinsic (e.g., gender, genotype, ethnicity, inherited diseases) or extrinsic (e.g., acquired disease states, xenobiotic exposure, diet) factors that may occur during the first 2 decades of life.

Selection of an appropriate drug dose for a neonate, infant, child, or adolescent requires an understanding of the basic pharmacokinetic properties of a given compound and how the process of development affects each facet of drug disposition. Accordingly, conceptualizing pediatric pharmacokinetics by examining the impact of development on the physiologic variables that govern ADME is most useful.

Drug Absorption

The rate and extent of gastrointestinal absorption depend primarily on pH-dependent passive diffusion and motility of the stomach and small intestine, both of which control transit time. In full-term neonates, gastric pH ranges from 6 to 8 at birth and drops to 2 to 3 within the first few hours. After the first 24 hours of extrauterine life, gastric pH increases to 6 to 7 as a result of immaturity of the parietal cells. A relative state of achlorhydria remains until adult values and diurnal patterns of gastric pH are reached at approximately 20 to 30 months of age. Although basal gastric acid output can be quite similar in neonates, young infants, and adults, stimulated acid output can be threefold to fourfold higher than that seen in adults.^{57,58}

TABLE 235.1 Summary of Drug Absorption in Neonates, Infants, and Children^a

	Neonates	Infants	Children
Physiologic Alteration			
Gastric emptying time	Irregular	Increased	Slightly increased
Gastric pH	>5	2–4	Normal (2–3)
Intestinal motility	Reduced	Increased	Slightly increased
Intestinal surface area	Reduced	Near adult	Adult pattern
Microbial colonization	Reduced	Near adult	Adult pattern
Biliary function	Immature	Near adult	Adult pattern
Muscular blood flow	Reduced	Increased	Adult pattern
Skin permeability	Increased	Increased	Near adult pattern
Possible Pharmacokinetic Consequences			
Oral absorption	Erratic: reduced	Increased rate	Near adult pattern
Intramuscular absorption	Variable	Increased	Adult pattern
Percutaneous absorption	Increased	Increased	Near adult pattern
Rectal absorption	Very efficient	Efficient	Near adult pattern
Presystemic clearance	Less than adult	Greater than adult	Greater than adult (increased rate)

^aThe direction of alteration is given relative to the expected normal adult pattern.

Modified from Ritschel WA, Kearns GL. Pediatric pharmacokinetics. In: Ritschel WA, Kearns GL, eds. *Handbook of Basic Pharmacokinetics*. 6th ed. Washington, DC: American Pharmaceutical Association; 2004:227-240.

In neonates, gastrointestinal transit time is prolonged as a result of reduced motility and peristalsis. Gastric emptying is both irregular and erratic and only partially dependent on feeding. Gastric emptying rates approximate adult values by the time the infant reaches 6 to 8 months of age. During infancy, intestinal transit time generally is reduced relative to adult values because of increased intestinal motility.¹¹⁹ In contrast to developmental changes in motility, histologic examination of the luminal absorptive surface suggests that the adult pattern of architecture (and hence absorptive surface area relative to body size) is present at birth.^{86,238} In neonates and young infants, additional factors, including diminished splanchnic blood flow, immature biliary function, variable microbial colonization, and an apparent reduction in the activity of intestinal drug-metabolizing enzymes, may play a role in intestinal drug absorption.^{44,187}

These developmental changes in gastrointestinal function and structure in the neonatal period and early infancy produce alterations in drug absorption that are quite predictable. In general, the oral bioavailability of acid-labile compounds (e.g., β -lactam antibiotics) is increased, whereas that of weak organic acids (e.g., phenobarbital, phenytoin) is decreased. For orally administered drugs with limited water solubility (e.g., phenytoin, carbamazepine), the rate of absorption (i.e., T_{max}) can be altered dramatically as a result of changes in gastrointestinal motility.¹⁸⁷ The pharmacokinetics of the antiviral agent pleconaril similarly provides an example of developmental differences in drug absorption. After administration of a 5 mg/kg dose, the AUC was much lower in neonates than either children or adults, thus demonstrating that the extent of pleconaril bioavailability in neonates was reduced. The reason for this difference may be attributed to the lipid-based pleconaril formulation and to developmental differences in the ability to absorb lipids as a consequence of biliary immaturity and reduced lipase secretion in neonates.¹²¹

In neonates and young infants, both rectal and percutaneous absorption is highly efficient for properly formulated drug products. The bioavailability of many drugs administered by the rectal route is increased as a result of not only efficient translocation across the rectal mucosa but also a reduced first-pass effect caused by the immaturity of a number of drug-metabolizing enzymes in the liver. Both the rate and extent of percutaneous drug absorption are increased because of the thinner and better hydrated stratum corneum in young infants. As a consequence, systemic toxicity can occur with the percutaneous application of some drugs (e.g., hexachlorophene) to seemingly small areas of skin during the first 8 to 12 months of life. In contrast to older infants and children, the rate of bioavailability for drugs administered by the intramuscular route may be altered (i.e., delayed T_{max}) more than the extent of absorption

FIG. 235.4 Body composition reflected as a percentage (y-axis) of total body mass for total body water, extracellular water, and body fat as a function of age (x-axis). (From Ritschel WA, Kearns GL. *Pediatric pharmacokinetics*. In: Ritschel WA, Kearns GL, eds. *Handbook of Basic Pharmacokinetics*. 6th ed. Washington, DC: American Pharmaceutical Association; 2004:227-240.)

in a neonate. This developmental pharmacokinetic alteration is the consequence of relatively low muscular blood flow in the first few days of life, the relative inefficiency of muscular contractions (useful in dispersing an intramuscular drug dose), and an increased percentage of water per unit of muscle mass.¹⁸⁷

Developmental differences in drug absorption among neonates, infants, and older children are summarized in Table 235.1. The data contained therein reflect developmental differences that may be expected to occur in healthy pediatric patients. Certain conditions or disease states that could modify the function or structure, or both, of the absorptive surface area, gastrointestinal motility, or systemic blood flow can further affect either the rate or the extent of absorption for extravascularly administered drugs in pediatric patients.

Distribution

Development is associated with marked changes in body composition as reflected by examination of total body water, extracellular water, and stores of body fat (Fig. 235.4). The most dynamic changes occur in the first year of life, with the exception of total body fat, which has a distinctly different pattern in male and female children. Furthermore, the adipose

TABLE 235.2 Plasma Protein Binding and Drug Distribution^a

	Neonates	Infants	Children
Physiologic Alteration			
Plasma albumin	Reduced	Near normal	Near adult pattern
Fetal albumin	Present	Absent	Absent
Total protein	Reduced	Decreased	Near adult pattern
Serum bilirubin	Increased	Normal	Normal adult pattern
Serum free fatty acids	Increased	Normal	Normal adult pattern
Blood pH	7.1–7.3	7.4 (normal)	7.4 (normal)
Possible Pharmacokinetic Consequences			
Free fraction	Increased	Increased	Slightly increased
Apparent volume of distribution			
Hydrophilic drugs	Increased	Increased	Slightly increased
Hydrophobic drugs	Reduced	Reduced	Slightly decreased
Tissue-to-plasma ratio	Increased	Increased	Slightly increased

^aThe direction of alteration is given relative to the expected normal adult pattern. Modified from Ritschel WA, Kearns GL. Pediatric pharmacokinetics. In: Ritschel WA, Kearns GL, eds. *Handbook of Basic Pharmacokinetics*. 6th ed. Washington, DC: American Pharmaceutical Association; 2004:227-240.

tissue of neonates may contain as much as 57% water and 35% lipids, whereas values in adults approach 26% and 72%, respectively.¹⁸⁷

In addition to age-related alterations in body composition, several physiologic changes that occur during the neonatal period are capable of altering the plasma protein binding of drugs (Table 235.2). In neonates, the free fraction of drugs that are bound extensively to circulating plasma proteins is increased markedly, largely because of lower concentrations of drug-binding proteins, reduced binding affinity of these proteins, the presence of a relatively acidic plasma pH, and endogenous competing ligands (e.g., bilirubin, free fatty acids). This consideration is exemplified by ceftriaxone, a weak acid that is approximately 95% bound to albumin in adults but only 70% bound in neonates and thus is capable of producing significant displacement of bilirubin.^{96,153} The reduced plasma protein binding, in combination with absolute and relative differences in the size of various body compartments (e.g., total body water, extracellular fluid, composition of body tissues), frequently influences (i.e., increases) the apparent VD for many drugs and also their localization (i.e., both uptake and residence) in tissue, which, in turn, can alter their plasma elimination half-life.

Renal Excretion

The renal excretion of many drugs is directly proportional to age-dependent patterns in the acquisition of renal function, primarily glomerular filtration and active tubular secretion. Accordingly, developmental differences in renal function may serve as a major determinant of drug clearance in neonates and young infants for compounds that are not metabolized extensively.¹⁸⁷

In preterm infants, renal function is reduced dramatically because of the continued development of functioning nephron units (i.e., nephrogenesis). In contrast, the acquisition of renal function in a term neonate represents, to a great degree, the recruitment of fully developed nephron units. In both term neonates and preterm infants who have birth weights greater than 1500 g, glomerular filtration rates increase dramatically during the first 2 weeks of postnatal life (Fig. 235.5). This particular dynamic change in function is a direct consequence of postnatal adaptations in the distribution of renal blood flow (i.e., medullary distribution to the corticomedullary border) and results in a dramatic recruitment of functioning nephron units.¹¹⁹ In addition, a glomerular-tubular imbalance exists in which the maturation of the glomerular function is more advanced than is the proximal tubular secretion. This imbalance may persist for up to 6 to 10 months of age, when both tubular function and glomerular function approach values approximately equal to those observed in healthy, young adults.¹⁸⁷

The impact of development on each of the components of renal function can be characterized by a definable pattern during the first year of life (see Fig. 235.5).¹⁷² Accordingly, the renal handling and, hence, excretion and elimination characteristics of virtually any drug

FIG. 235.5 Ontogeny of renal function. *Cl*, Clearance; *GFR*, glomerular filtration rate; *PAH*, *p*-aminohippuric acid. (Modified from Papadopoulos ZL, Tina LU, Sandler P, et al. Size and function of the kidneys. In: Johnson TR, Moore WM, Jeffries JE, eds. *Children Are Different: Developmental Physiology*. 2nd ed. Columbus, OH: Ross Laboratories; 1978:97-104.)

in neonates, infants, and children can be predicted largely by considering the ontogeny of renal function and the specific pharmacologic characteristics of a given drug with regard to its renal excretion (e.g., routes of renal excretion, the percentage of a given dose excreted unchanged in urine) in adults. For antimicrobial agents, the impact of the ontogeny of the renal function on pharmacokinetics is reflected largely by alterations in the plasma drug clearance. As summarized by van den Anker and Kearns,²²⁸ the elimination half-life of antimicrobial agents from different classes that share predominantly renal pathways of excretion is increased substantially in neonates and young infants (Table 235.3). This increase is not the case for antimicrobial and other agents that are not excreted primarily by the kidneys (e.g., ceftriaxone).

Metabolism

Simply stated, drug metabolism (or biotransformation) involves the modification of a drug molecule by one or more enzymes such that the hydrophilicity of the product is increased relative to the parent drug, thus enhancing elimination and excretion. In most instances, drug metabolism creates products that are either less pharmacologically active than is the parent drug (e.g., desacetyl cefotaxime) or devoid of pharmacologic activity altogether (e.g., cefotaxime lactone metabolites).¹¹⁸ In other instances, metabolism can result in drug bioactivation and produce metabolites with pharmacologic activity from an inactive parent drug (i.e., prodrug), such as inactive valganciclovir activated to

TABLE 235.3 Impact of Ontogeny on the Elimination Half-Life of Drugs With Predominant Renal Routes of Excretion^a

Drug	Cl (mL/h/kg)	VD (mL/kg)	ELIMINATION $t_{1/2}$ (h)	
			Neonate	Adult
Gentamicin	35–72	350–500	4.4–11.4	2.5
Tobramycin	41–74	590–840	8.2–11.3	2.0
Amikacin	50	570	8.4	2.5
Cefotaxime	50–100	310–790	3.4–6.4	1.2
Ceftriaxone	44–60	530–610	7.7–8.4	6.5

ganciclovir, or the generation of metabolites that can result in cellular toxicity in the host (e.g., sulfamethoxazole's nitroso and hydroxylamine reactive metabolites, acetaminophen's NAPQI reactive metabolite).

Virtually every tissue has some ability to carry out drug biotransformation reactions. Although the liver is quantitatively the most important organ capable of drug metabolism, the small intestine, lungs, skin, and kidneys also have substantial drug biotransformation activities. In infants, children, and adolescents, developmental variations in drug metabolism have been associated with age, sex, maturation, and genetic constitution. For compounds that are extensively metabolized, developmental differences in drug metabolism can serve as the primary determinant for age-appropriate dose selection.¹³⁷ Much of the existing information regarding the impact of ontogeny on drug metabolism has been derived as a byproduct of pharmacokinetic investigations designed, in part, to determine whether age-dependent differences in drug disposition were evident.¹¹⁹ The following paragraphs highlight important general issues regarding drug metabolism and its relationship with development.

PHASE I PATHWAYS

Phase I biotransformation reactions include oxidation, reduction, and hydrolysis reactions that, in general, introduce or unmask a functional group (e.g., hydroxyl, amine, sulfhydryl) that renders a drug more polar. Quantitatively, the P-450 cytochromes are the most important of the phase I enzymes and represent a superfamily of heme-containing proteins that catalyze the metabolism of many lipophilic endogenous substances (e.g., steroids, fatty acids and fat-soluble vitamins, prostaglandins, leukotrienes, and thromboxanes) and exogenous compounds. In humans, the P-450 cytochromes can be divided functionally into two distinct classes: steroidogenic enzymes expressed in specialized tissues, such as the adrenal glands, gonads, and placenta; and enzymes involved in the metabolism of drugs, pesticides, and environmental contaminants. P-450 cytochromes that have been identified as important in human drug metabolism are found predominantly in the *CYP1*, *CYP2*, and *CYP3* gene families.¹³⁷

As reviewed by Leeder and Kearns,¹³⁷ considerable interindividual variability exists in the hepatic expression of P-450 enzymes, and, for a given individual, the pathway and rate of a compound's metabolic clearance constitute that individual's unique phenotype with respect to the forms and amounts of P-450 isoforms expressed. Of the P-450 cytochromes involved in drug biotransformation, CYP2C19, CYP2C9, and CYP2D6 are examples of isoforms that are polymorphically expressed in humans. Polymorphic expression of CYP1A2 and CYP3A4 has been reported in the literature but not definitively established with regard to functional consequences. Within a P-450 subfamily, several isoforms can exist (e.g., CYP3A4, CYP3A5, and CYP3A7), each of which can demonstrate substrate specificity and a distinct developmental pattern with regard to enzyme activity. In addition, certain P-450 cytochromes

(e.g., CYP3A4) can work cooperatively with transporters (e.g., MDR-1 or P-glycoprotein) located in distinct cells or tissues to alter the availability of specific drugs to the systemic circulation (e.g., first-pass metabolism of CYP3A4 substrates in the enterocyte). Moreover, for certain polymorphically expressed P-450 cytochromes (e.g., CYP2C19, CYP2D6), enzyme activity has been shown to vary as a consequence of racial or ethnic origin¹⁸³ and, within a given phenotypic distribution (e.g., extensive metabolizers for CYP2D6), as a function of single nucleotide polymorphisms that exist in either the gene or its regulatory regions.¹⁸¹ Finally, throughout development, the activities of the P-450 cytochromes can vary widely (e.g., 5- to 25-fold) among individuals of the same phenotype,¹³⁷ an important factor with respect to the ability for induction or inhibition and, thus, the prediction of drug-drug or drug-xenobiotic interactions in vivo.

PHASE II PATHWAYS

In general, phase II reactions involve the coupling of a drug or drug metabolite with an endogenous substance to enhance its hydrophilicity further and to facilitate drug excretion in either urine or bile. These reactions require the participation of specific transferase enzymes (e.g., epoxide hydrolase, glucuronosyltransferases, glutathione S-transferases, sulfotransferases, N-acetyltransferases, methyltransferases, transacylases) and high-energy, activated endogenous substances. Although most conjugation reactions result in drug detoxification, examples of bioactivation by phase II enzymes do exist.¹⁸⁶ Similar to what has been found for certain of the P-450 cytochromes, different isoforms of phase II enzymes also occur in humans. This finding is exemplified by the review of de Wildt and colleagues,⁴⁵ who described substrate specificity for 10 different glucuronosyltransferase isoforms in humans and known polymorphisms in five different isoforms of this enzyme. The impact of age on the disposition of several glucuronosyltransferase substrates (e.g., morphine, acetaminophen, zidovudine, chloramphenicol) suggests that isoform-specific, age-related differences in activity occur to a degree sufficient to produce profound effects on drug clearance that translate directly into age-specific differences in a drug dose.⁴⁵

Normal growth and development can have a profound effect on the activity of drug-metabolizing enzymes. Failure to recognize important developmental differences in drug biotransformation and to appropriately compensate for them by individualizing drug dosing can lead to serious consequences. This is exemplified by the "gray baby syndrome" previously associated with chloramphenicol, which is a life-threatening adverse drug reaction that was associated with supratherapeutic systemic drug exposure and, in some infants, produced cyanosis and cardiovascular collapse. The genesis of this particular toxicity resided with normal developmental reductions in the activity of the glucuronosyltransferase isoforms responsible for metabolizing chloramphenicol and the failure to appropriately adjust the dosing schedule to compensate for reductions in systemic clearance.^{61,239}

Traditionally, the impact of ontogeny for all enzymes was viewed as being extremely limited in neonates, rapidly increasing in the first year of life to levels in toddlers and older children that may exceed adult capacity, and declining to adult levels by the conclusion of puberty. Experimental and clinical data previously reviewed demonstrated that this theory is not accurate.^{119,137} As illustrated by the summary data contained in Table 235.4, the impact of ontogeny on the activity of both phase I and phase II drug-metabolizing enzymes is very much a substrate- and isoform-specific event; development is one dynamic factor in a multitude of conditions (e.g., nutritional status, gender, diurnal variation, menstrual cycle, disease states/organ dysfunction, pregnancy, concomitant drug therapy) capable of altering the activity of drug-metabolizing enzymes and, thus, the clearance of drugs (and their metabolites) from plasma. Although discussion of the impact of ontogeny on the disposition (pharmacokinetics) of specific drugs is beyond the scope of this chapter, the clinician can use much of the information concerning specific enzymes provided in Table 235.4 as a tool to facilitate inquiry or clinical decision making, or both. It can be done simply by using readily available, updated information describing which enzymes are responsible for drug metabolism and then searching the published or unpublished (e.g., information available from

TABLE 235.4 Developmental Patterns for the Ontogeny of Important Drug-Metabolizing Enzymes in Humans

Enzyme(s)	Known Developmental Pattern
Phase I Enzymes	
CYP2D6	Low to absent in fetal liver but present at 1 wk of age; poor activity (i.e., 20% of adult) by 1 mo; adult competence by 1 to 3 y of age
CYP2C9	Apparently absent in fetal liver; low activity in first 2 to 4 wk of life, with adult activity reached by approximately 6 mo; activity may exceed adult levels during childhood and declines to adult levels after conclusion of puberty
CYP1A2	Not present in appreciable levels in human fetal liver; adult levels reached by approximately 4 mo and exceeded in children at 1 to 2 y of age; adult activity reached after puberty
CYP3A7	Fetal form of CYP3A that is functionally active (and inducible) during gestation; virtually disappears by 1 to 4 wk of postnatal life when CYP3A4 activity predominates but remains present in approximately 5% of individuals
CYP3A4	Extremely low activity at birth, reaching 30% to 40% of adult activity by 1 mo and full adult activity by 6 mo; may exceed adult activity between 1 and 4 y of age and decrease to adult levels after puberty
Phase II Enzymes	
NAT2	Some fetal activity by 16 wk of gestation; poor activity between birth and 2 mo of age; adult phenotype distribution reached by 4 to 6 mo, with adult activity reached by 1 to 3 y
TPMT	Fetal levels approximately 30% of adult values; in newborns, activity approximately 50% higher than in adults, with phenotype distribution approximating that of adults; exception is Korean children, in whom adult activity is seen by 7 to 9 y of age
UGT	Ontogeny isoform specific; in general, adult activity reached by 6 to 24 mo of age
ST	Ontogeny isoform specific and appears faster than that for UGT; activity for some isoforms may exceed adult levels during infancy and early childhood

CYP, Cytochrome P-450; NAT2, *N*-acetyltransferase-2; ST, sulfotransferase; TPMT, thiopurine methyltransferase; UGT, glucuronosyltransferase.

pharmaceutical companies for drugs under development) literature for information describing the pharmacokinetics of the drug being considered.

Clinicians must recognize that age-dependent differences in the activity of enzymes that catalyze drug biotransformation are not limited solely to P-450 cytochromes or the host of transferase enzymes responsible for phase II drug metabolism, and, in many cases, these differences represent a critical determinant for successful antiinfective drug therapy. This factor is exemplified by considering the example of two antimicrobial agents that have unique places in pediatric therapy: cefotaxime and linezolid. In the case of cefotaxime, non-P-450 enzymes (probably an esterase) capable of generating the active desacetyl cefotaxime metabolite appear to be present and fully active by the third trimester of gestation.¹²³ Nonetheless, the elimination half-life of cefotaxime in neonates is approximately threefold greater (i.e., 3–4 hours) than that observed in older infants and children (i.e., 1–1.5 hours), a difference that permits extension of the dosing interval for the use of cefotaxime in neonates. The reasons for this developmental difference reside not with the enzymes responsible for generation of an active metabolite; instead, age-associated reductions in the activity of enzymes appear to be responsible for the

generation of inactive metabolites of cefotaxime (e.g., cefotaxime lactone) and pathways involved in the renal clearance of desacetylcefotaxime.¹²² Linezolid, an oxazolidinone antimicrobial approved in the United States for use in pediatric patients, undergoes extensive biotransformation in humans, not through a cytochrome P-450 enzyme, but rather by nonselective chemical oxidation.¹²⁵ As demonstrated by Kearns and associates,¹²⁰ the mean plasma clearance of linezolid in children was approximately threefold higher than that observed previously for adults, with the greatest increase noted in infants younger than 1 year. Given the mechanism of action for linezolid and properties that reflect time-dependent killing,¹²⁵ the clinical implications of the age-dependent pattern of increased plasma clearance for this drug in young infants and children suggest that for infections with selected pathogens that have relatively high (90%) minimal inhibitory concentration (MIC₉₀) values for the drug, shorter dosing intervals (e.g., every 8 hours) may be necessary to ensure sufficient exposure of the organism in blood and tissue through most of a dosing interval.¹²⁰

PHARMACOKINETIC DETERMINANTS OF EFFECT

Collectively, the most important determinants of efficacy for antiinfective agents are the pharmacokinetic profile of the drug, the physicochemical and biochemical characteristics of the local environment (i.e., site of infection), and the susceptibility of the infecting organisms under local growth conditions. As previously reviewed by Barza,¹⁷ the mechanisms and pharmacokinetics of drug transport to and accumulation at the site or sites of infection, as well as the subcellular localization of drugs, are critical to success and are poorly understood. In many circumstances, plasma drug concentrations may not be reflective of those in tissue. Pathophysiologic processes related to the host, the infection, and the physicochemical properties of the drug work in concert to regulate distribution into and retention of active drug at the site of infection. Because these considerations should be embraced by the clinician when a particular antiinfective drug is selected for treatment and its therapy is monitored for clinical evidence of success, some general examples are presented as follows.

In addition to age (as discussed earlier), many disease processes (e.g., trauma, malignancy, renal or hepatic disease) have an impact on both the quantity of circulating plasma proteins (e.g., albumin, α_1 -acid glycoprotein) and their affinity to bind antiinfective agents. Given that only free drug is available to enter tissue, the degree of binding to protein components in the blood will affect tissue concentrations. Thus, despite the presence of total (i.e., free and bound) plasma drug concentrations well in excess of the MIC, these concentrations may not be predictive of concentrations of highly bound (i.e., >70%) drug at the site of infection. Properties of the capillary bed feeding the site of infection also dictate drug penetration. Highly vascularized tissue with a large ratio of capillary surface area to volume can be expected to accumulate higher drug concentrations than can tissue that is poorly vascularized, principally because of the rate and extent to which drug can be delivered to the site. As with protein binding, variability in capillary density may be a function of disease (e.g., severe atherosclerosis, diabetes), infection (e.g., abscess, cardiac vegetation), and age, and it should be expected to have an impact on drug delivery. Similarly, tissues with tight junctions and few fenestrations (e.g., eye, central nervous system [CNS]) afford lower tissue concentrations, given that drug entry is restricted to transport across the lipid bilayer of the endothelial cell (i.e., transcellular vs. paracellular transport). Here, adequate drug penetration is restricted to agents with a favorable lipid-water partition coefficient and ionization constant. As such, many infectious processes warrant direct instillation of antibiotic at the site of infection (e.g., intracisternal, intrathecal, intraarticular). Additionally, cellular transporters (e.g., P-glycoprotein at the blood-brain barrier, organic anion and cation transporters at the choroid plexus) capable of pumping drug from the cell can limit distribution and retention of drug at the tissue level. The pH at the site of infection (e.g., in tissue fluids, exudates, transudates) relative to the pH in plasma also can govern distribution of a drug. For example, in cases of bacterial meningitis, the pH that occurs in the CNS is lower relative to plasma. Weak acids (e.g., penicillin) are more highly ionized in plasma than in cerebrospinal fluid (CSF) and pass more readily from the CSF

into plasma than in the reverse direction. Similarly, when the pH of the local environment drops in the presence of infection, as occurs in lung abscesses, aminoglycoside efficacy is reduced because of chemical inactivation of the drug by ionization and the formation of stable adducts with high DNA concentrations found in purulent secretions. Finally, the physicochemical association of an intact (i.e., unmetabolized) drug with a particular physiologic fluid as part of its normal excretion profile can serve to localize drug at the site of infection (e.g., accumulation of drugs excreted by the biliary route in patients with cholangitis and in the urine in patients with nephritis). It is important to recognize that such interactions modify the activity of antimicrobial agents. For example, in vitro data demonstrate that daptomycin interacts with pulmonary surfactant, which in turn decreases the activity of the antibiotic. Hence the drug is not currently indicated in the treatment of pulmonary infections.²⁰⁷ When drug-tissue and drug-body fluid interactions occur, different approaches, including dose modification or combination therapy, may need to be considered to optimize therapy.

PHARMACODYNAMIC DETERMINANTS OF EFFECT

The desired effect of any drug is realized when sufficient concentrations are achieved and maintained at the active site for an adequate period. In many models of disease for which the treatment targets of modern chemotherapy remain fixed, the concentration-effect (i.e., pharmacodynamic) relationships can be described with relatively modest effort. In contrast, evaluating the concentration-effect relationship for antimicrobial agents can be anything but straightforward, given the dynamic nature of infection. The intended target of the antiinfective agent is in constant flux as the number of organisms changes, the quantity and affinity of target receptors evolve, and the contribution of the host response adapts accordingly during the course of infection. Moreover, antimicrobial agents demonstrate variable effects at different concentrations and under different physicochemical environments. In fact, evaluating whether an organism survives in the presence of antibiotic is only one criterion by which to predict or define drug effect. Rather, a variety of effects related to antimicrobial concentration—from the extremes of complete eradication to complete survival—can be observed in the invading organism. The previous sections of this chapter review the principles of pharmacokinetics, specifically, factors that link dose to concentration. The sections that follow include a discussion of the pharmacodynamics of antiinfective therapy and the multitude of factors that link concentration with effect.

Effects Described by Pharmacokinetic Parameters and Conventional Susceptibility End Points

Among the many decision-making tools that clinicians have at their disposal to guide in the selection of antimicrobial therapy are qualitative (e.g., breakpoints) and quantitative (e.g., MIC, minimal bactericidal concentration [MBC]) estimates of susceptibility. Although numerous studies and years of clinical evidence support the correlation between qualitative end points and clinical outcome, their predictive power is diminished in the presence of immunocompromise, severe underlying disease, mixed infections, and infection with organisms demonstrating heterogeneous resistance patterns.^{34,40,64,146,155} Quantitative end points provide a better assessment of dose-effect relationships, with antibiotic concentration serving as a surrogate for the dose. However, these data alone do not reveal the complete picture relative to the anticipated bacterial response because laboratory-based quantitative tests contain a notable number of artificial aspects. Factors appreciated to influence the activity of antimicrobial agents in vivo (e.g., protein binding, fluctuating drug concentrations, serial drug exposure, inoculum size, immune defense status, physicochemical environment, compound stability) essentially are neglected when determining MIC values. As such, agents with comparable MIC values in vitro may, in fact, demonstrate markedly different effect profiles in a patient.^{3,33,70,113,130}

In an attempt to move beyond reliance on quantitative tests as the sole marker for predicting antimicrobial activity in vivo, the integration of susceptibility information with population- and patient-specific pharmacokinetic data continues to be explored. Surrogate end points,

FIG. 235.6 Representative plasma concentration versus time curve illustrating commonly referenced pharmacodynamic parameters. *AUC*, Area under the curve; *C_{max}*, maximal plasma concentration; *MIC*, minimal inhibitory concentration; *T*, time.

defined by a combination of pharmacokinetic parameters and quantitative susceptibility data, have been suggested to predict more reliably the efficacy of different antimicrobial agents. By far, pharmacodynamic determinants of antimicrobial effect most frequently link attainable drug concentrations or estimates of total body exposure, or both, with in vitro estimates of pathogen sensitivity. For antimicrobial agents for which the mechanism of action is determined to be time dependent (concentration independent), the percentage of time that plasma or tissue concentrations remain above the MIC has been closely linked to therapeutic response (Fig. 235.6). By comparison, the ratio of *C_{max}* to MIC has demonstrated a similar relationship for drugs with concentration-dependent killing (see Fig. 235.6). Furthermore, the ratio of *AUC* to MIC, which reflects the concentration profile over the course of time, has been used with both classes of agents (see Fig. 235.6).

Evidence to support the application of specific pharmacodynamic surrogates is reviewed in the following paragraphs. However, a large degree of interdependence exists among these pharmacokinetic parameters. With few exceptions, when the dose of a drug is increased, *C_{max}* and the total *AUC* increase, and with no change in clearance, so, too, does the percentage of time that plasma drug concentrations remain above the MIC. Accordingly, making distinctions among the various pharmacokinetic parameters in an attempt to determine the optimal pharmacodynamic end point can be misleading. Given that many studies evaluate a limited number of doses or dosing intervals, restrict the number of pharmacokinetic parameters that are calculated, or neglect to perform multivariate analysis on the data, clear distinctions between parameters cannot always be made, and an appropriate degree of caution should be exercised when evaluating such data.²³³

Time Above the Minimal Inhibitory Concentration

Among the first class of antimicrobial agents to be discussed in the context of their concentration-effect relationships were the β -lactams, specifically penicillin. Although limited supporting evidence existed at the time, investigators were concerned with maintaining adequate blood levels of the drug in the host for a fixed period of time. This concern was reflected in their attempts to inhibit clearance pathways and formulate sustained-release preparations designed specifically for the purpose of extending the time spent above some minimal concentration ($T > MIC$).^{21,190} As it turns out, in vitro studies support the relative concentration independence of penicillin and demonstrate that a maximal rate of killing can be observed that is quickly saturated at reasonably low multiples of the MIC (Fig. 235.7A). As concentrations increase above this maximal level, no faster rates of kill can be demonstrated.³⁷ Rather, penicillin displays time-dependent killing in which the duration of time spent above some minimal concentration (typically ± 1 to 2 dilutions of the MIC or MBC) appears to be the most important determinant of activity.⁵³ As newer antimicrobial agents with putative time-dependent

FIG. 235.7 Representative log-kill curves. These curves illustrate the response to (A) concentration-independent (time-dependent) and (B) concentration-dependent antimicrobial agents. *MIC*, minimal inhibitory concentration. (Modified from Craig WA, Ebert SC. Killing and regrowth of bacteria in vitro: A review. *Scand J Infect Dis*. 1991;74[Suppl]:63-70.)

activity became available for evaluation, those with longer plasma and tissue terminal elimination half-lives demonstrated enhanced bactericidal activity compared with similar drugs. Those that simply resulted in higher maximal peak concentrations, with no extension of the time above the MIC, produced minimal if any differences in effect.^{12,87,197,240} This time-dependent activity has been observed in vitro with virtually all β -lactams (e.g., cephalosporins, carbapenems, monobactams) against both gram-positive and gram-negative organisms.^{65,87,212,247} Similarly, other drug classes, namely, the macrolides, azalides, glycolcyclines, glycopeptides, ketolides, and oxazolidinones, appear to possess this same characteristic.^{10,93,150,229,231}

When evaluating whether the time-dependent activity observed in vitro can be reproduced in vivo by evaluating intrinsic antibiotic activity in the host (through restriction of observations to animals in which the element of both humoral and cell-mediated immunity has been removed), the strongest relationship between antimicrobial concentration and effect for the aforementioned agents remains the time spent above the MIC.¹⁹³ Elegant studies evaluating extensive numbers of dosing regimens and drug-microbe combinations demonstrated that β -lactam and macrolide efficacy correlates best with the percentage of time spent above the MIC, irrespective of whether gram-positive or gram-negative pathogens are involved.²³³ Given the same total daily dose, therapy administered at more frequent intervals is required for a successful outcome.^{14,138} Even when the drug-microbe interaction is such that only bacteriostatic activity results, a regimen consisting of more frequent doses is able to maintain an environment of no net growth, whereas positive net growth is observed with larger doses administered less frequently.⁷⁹ From such data, the efficacy of time-dependent agents appears to be maximized by maintaining antibiotic concentrations above the MIC for as much of the dosing interval as possible.

When evaluating whether these agents obey the same relationship in the presence of a competent immune system, animal models similarly demonstrate a significant correlation between antimicrobial efficacy and the percentage of time spent above the MIC.^{4,71} In contrast to immunocompromised animals, animals with a functional immune system do not require that virtually 100% of the dosing interval be spent above the MIC to achieve adequate antimicrobial activity. Although the bactericidal activity of penicillin ceases when concentrations fall below the MIC, the remaining organisms do not resume multiplication for many hours, well in excess of the time observed for the same

organisms in vitro.^{55,114} This difference may reflect the time required for the organism to recover from the initial antibiotic insult, coupled with the complementary activity of subinhibitory antibiotic concentrations and the immune system (these pharmacodynamic principles are explored later in further detail).⁷⁶ Irrespective of the mechanism by which the protracted antimicrobial effect occurs, the pharmacodynamic goals for time-dependent agents are not as stringent in vivo as they are in vitro. However, the persistent suppression of bacterial growth is not indefinite, and a maximal amount of time can be spent below the MIC before a reduction in efficacy becomes apparent. Thus a maximal dosing interval for these agents appears to exist in immunocompetent hosts, beyond which a decrease in efficacy can be expected.^{54,202}

Clinical studies further confirm that for the agents discussed earlier, time above the MIC is a suitable pharmacodynamic end point in patients. In clinical studies of upper respiratory tract infection, the highest bacterial eradication rates for the β -lactams are observed when the time above the MIC exceeds 40% to 50% of the dosing interval.⁴¹ For cefuroxime, cure rates drop from greater than 90% to approximately 75% when the time above the MIC falls to less than 40%.^{74,83} Patients infected with a susceptible organism show 92% efficacy with a continuous-infusion regimen of cefamandole versus 63% efficacy with intermittent administration of the agent. Finally, in neutropenic patients, an overall efficacy rate of 65% was observed after continuous infusion of cefamandole as opposed to 21% efficacy in patients receiving intermittent administration.²⁸ For macrolide-susceptible pathogens, cure rates approaching 100% were observed when concentrations remained above the MIC for greater than 80% of the dosing interval.⁴¹ As the MIC increases such that the percentage of time spent above the MIC falls, so, too, do cure rates. Macrolide concentrations rarely exceed the MIC for *Haemophilus influenzae*, and cure rates are comparable to those seen in placebo-treated individuals.⁴¹ A few studies appear to contradict the aforementioned data, findings indicating that little difference in clinical response is observed when the same total daily dose of selected agents is administered as a continuous infusion or with increased frequency versus less frequent intermittent administration; however, a prolonged postantibiotic effect (PAE) or protracted half-life, such that both of the regimens evaluated spend nearly 100% of the dosing interval above the MIC, may explain these discrepancies.^{32,133,234}

A natural extension of the considerations just discussed relates to the utility of continuous infusions for antimicrobial agents that exhibit

time-dependent killing, a topic that has historically been controversial. Theoretically, continuous drug administration would ensure that serum concentrations and potentially those at the site of action would never fall below the MIC. This would be of particular value for antimicrobial agents with a short half-life, in patients in whom drug exposure is limited based on increased volumes of distribution or clearance rates, and in patients who have a significant degree of immunocompromise. Although the benefits appear obvious, the clinical findings are often equivocal, with data both supporting and refuting improvement in clinical outcomes related to continuous antimicrobial administration. Because of the relative dearth of new antimicrobial development and the ever-increasing cases of multidrug-resistant organisms encountered, application of extended or continuous infusions in clinical care continues with attempts of more rigorous evaluation of pharmacodynamic and clinical outcome results. These studies include designed randomized control trials, with further evaluation in different patient populations, including children.^{50,59} Variability in antibiotic dosing, disease severity, causative bacterial pathogens, and susceptibility patterns all add to the complexity of accurately assessing prolonged infusions.¹⁸⁹ Moreover, challenges encountered with the administration of continuous infusions of antimicrobial agents include obtaining adequate serum concentrations, drug stability, practicality of administration, and potential adverse reactions associated with prolonged drug exposure. Consequently, clinical guidelines for the application of continuous infusions are lacking, and additional data are needed to better understand the potential advantages and disadvantages of continuous infusions, particularly in the setting of more highly resistant pathogens and in complex pediatric patient populations.

Concentration Above the Minimal Inhibitory Concentration

In contrast to the aforementioned agents, a smaller group of agents demonstrate concentration dependence, with the magnitude of antimicrobial effect increasing in direct proportion to increasing drug concentrations (Fig. 235.7B).^{20,152} The aminoglycoside and fluoroquinolone antibiotics are the prototypic drugs of this pharmacodynamic class; however, concentration-dependent activity also has been observed with the lipopeptides, metronidazole, and the echinocandins.^{7,43,149,180,211,230} Unlike the time-dependent agents, for which shortening the dosing interval results in increased efficacy, extending the dosing interval for concentration-dependent drugs affords an ability to increase the dose and results in a greater reduction in bacterial inoculum and, for some agents, a diminution in adaptive resistance.⁴² Although highly variable, optimal ratios of peak plasma concentration to MIC that result in complete killing have been defined for many drug-microbe combinations. Similarly, ratios of C_{max} to MIC (C_{max}/MIC) can be defined, below which the organism is afforded the opportunity to regrow with increased selection of resistant subpopulations.^{26,48,49}

Concentration-dependent killing for many of these agents has been demonstrated in both animal models and human clinical trials. In neutropenic mice with pseudomonal soft tissue infection, dosing schemes that deliver larger aminoglycoside doses less frequently result in greater killing than do schemes with the same total daily dose administered more frequently, even though all regimens achieved serum concentrations in excess of the MIC.⁷⁹ Additionally, once-daily dosing of aminoglycosides has been associated with less toxicity compared with multiple daily dosing.^{18,209} In patients receiving quinolone therapy for the treatment of respiratory tract, urinary tract, and skin and soft tissue infections, several pharmacodynamic parameters proved to correlate with clinical response; however, the best correlation was observed with the C_{max}/MIC ratio.¹⁷⁸ In clinical trials in which patients received aminoglycoside therapy for gram-negative infections, the strongest association between pharmacokinetic indices and clinical response was observed with the C_{max}/MIC ratio. In fact, the relationship between the C_{max}/MIC ratio and clinical response appeared to be linear over the range of clinically relevant plasma concentrations. No significant difference occurred in the time to achieve C_{max} between responders and nonresponders; therefore the improved response rates in patients achieving higher peak plasma concentrations were not simply an artifact of drug accumulation as a result of longer duration of therapy.^{159,160}

In addition to the absolute peak plasma concentration, the time that optimal peak levels are achieved appears to play a critical role in

the response to concentration-dependent antimicrobial agents. A significant correlation with clinical improvement and reduction in mortality is observed if therapeutic peak plasma concentrations are reached early during the course of treatment.^{161,164} The probable reason for this effect is that the response of the bacterial population to the same antibiotic concentration can change with subsequent doses. As alluded to earlier, subtherapeutic peak plasma concentrations serve to select out fewer susceptible variants within the population.^{26,27,78} Based on these data, a key goal of therapy (i.e., in addition to proper drug selection) for concentration-dependent agents appears to be the attainment of high peak plasma concentrations early in therapy to afford rapid initial killing and minimize adaptive resistance.

Although prolonging the dosing interval affords the luxury of increasing the dose to optimize killing, the law of diminishing returns applies even for concentration-dependent agents, and it is possible to increase the dosing interval to excess and decrease efficacy. Despite the clear concentration dependence with escalating doses of fluoroquinolones, a simulated every-12-hour regimen was less effective than was a regimen using the same total daily dose administered every 8 hours.¹⁹ Similarly, animal models of gram-negative lung and soft tissue infection suggest that delayed clearance of the infecting organism is observed in response to aminoglycoside and fluoroquinolone therapy when administered in protracted dosing regimens (e.g., dosing interval much greater than the half-life) as opposed to shorter dosing intervals.^{138,163,191} Again, scattered studies appear to contradict these findings; however, they use agents with a longer half-life, and therefore the dosing interval may, in fact, not exceed the time spent above the MIC plus the residual PAE.⁴⁶ Thus, despite their concentration dependence, an element of time appears to be involved in the response to these agents. Unless peak concentrations are achieved in excess of those necessary to obtain maximal kill rates and the dosing interval does not markedly exceed time above the MIC plus the PAE, the efficacy of such agents is not only dose dependent but also dose interval dependent.

Total Body Exposure Above the Minimal Inhibitory Concentration

The AUC, a reflection of total body exposure, is a pharmacokinetic parameter that integrates both time and drug concentration. Estimates of AUC reflect the magnitude of the dose received and the drug half-life relative to the dosing interval. Accordingly, researchers have proposed that the ratio of AUC to MIC (AUC/MIC ratio) may serve as a better surrogate of pharmacodynamic activity for both time- and concentration-dependent agents. In several studies, the AUC/MIC ratio serves as the best correlate of the reduction in number of organisms for aminoglycosides, quinolones, streptogramins, rifamycins, isoniazid, evernimicin, echinocandins, and azole antifungal agents.^{6-9,47,60,115,116,173} Because of the interdependence between AUC and the pharmacokinetic parameters previously noted, studies also can be identified that demonstrate a relationship between clinical or microbiologic outcome and the AUC/MIC ratio for agents with time-dependent activity (e.g., the β -lactams and glycopeptides). Often, however, these studies fail to evaluate multiple pharmacokinetic parameters.^{158,201}

In an elegant study evaluating certain aminoglycoside dosing regimens against *Pseudomonas aeruginosa* and *Escherichia coli* infection, the log-normalized AUC provided the best correlation with efficacy. However, as was observed with concentration-dependent agents, when the dosing interval exceeded the time above the MIC plus the residual PAE, the best correlation with efficacy was the percentage of time spent above the MIC, thus reaffirming that the dosing interval can be too long with the aminoglycosides.²³³ A meta-analysis of 19 studies evaluating eight quinolones and six different organisms in experimental endocarditis similarly demonstrated a correlation between the AUC/MIC and reduction in log₁₀ colony-forming units (CFUs) per vegetation. However, given the relationship between the pharmacokinetic parameters, C_{max}/MIC and time greater than MIC also proved to correlate with a decrease in the size of the inoculum.⁵ In human investigations, AUC/MIC appears to serve as the best predictor of clinical response, microbiologic response, and bacterial eradication for the fluoroquinolones. Nonetheless, C_{max}/MIC and time greater than MIC can be linked similarly to bacterial eradication for this class of agents.^{68,69,175}

Clearly, the optimal AUC/MIC ratio will be different for different organisms despite sharing a similar quantitative susceptibility end point.

Similarly, optimal AUC/MIC ratios are highly variable and depend on the antimicrobial agent being evaluated. For example, effective eradication of organisms implicated in nosocomial pneumonia is observed with an AUC/MIC ratio of 540 for cefmenoxime, 34 for tobramycin, and 23 for ciprofloxacin.²⁰⁰ Consequently, attempts have been made to standardize this pharmacodynamic end point, and investigators have proposed a value of 125 as the cutoff below which a reduction in efficacy and increase in resistance may be expected.^{106,199} However, optimal AUC/MIC ratios may differ, depending not only on a given organism and agent but also on the desired outcome and the disease state. A ratio greater than 125 resulted in bacterial eradication roughly 7 days after the initiation of β -lactam and quinolone therapy; however, an AUC/MIC ratio of 250 resulted in eradication of the pathogen within 1 to 2 days after initiating quinolone therapy.¹⁹⁹ For patients with acute exacerbations of chronic bronchitis who are receiving fluoroquinolones, an AUC/MIC ratio less than 276 was associated with longer time to clinical success, whereas a ratio greater than 576 was associated with a reduction in coughs per day and a ratio greater than 212 with decreasing days to a reduction in the volume of sputum.¹⁵⁶ In an animal model of bacterial endocarditis, significantly lower numbers of organism were found in the vegetation after 3 to 6 days of therapy when the AUC/MIC ratio exceeded 100.⁵ Moreover, a value of 100 appeared to be the cutoff below which an increased risk for resistance was observed in a retrospective review of 107 acutely ill patients with lower respiratory tract infection.²²³ Furthermore, in vitro models evaluating fluoroquinolone activity against *Streptococcus pneumoniae* demonstrated effective eradication with an AUC/MIC ratio between 30 and 65, much lower than the value of 125 reported as optimal for other pathogens.^{132,142}

Although this hybrid parameter bridges concentration and time (i.e., extent of systemic drug exposure from a given dose) and has been demonstrated to correlate with efficacy for numerous drug classes, optimal criteria appear to vary with the organism, agent, disease state, and desired outcome. In addition, established relationships no longer may hold for some agents when a protracted dosing interval is used in therapy. As such, a general classification and standard outcome are not straightforward, and agents need to be evaluated with respect to known mechanisms of activity and the specific clinical and microbiologic situations in which they are used.

Optimal Surrogates for Drugs in Combination

Combination antimicrobial therapy is initiated in numerous circumstances: to ensure broad-spectrum coverage early in therapy, to treat polymicrobial infections, and to combat organisms that require multiple agents for effective eradication. Often, combination therapy entails the use of agents from different classes or agents that have different mechanisms of action (or both). This particular situation raises the question of how one applies the aforementioned pharmacodynamic principles to selecting or evaluating the efficacy of drug therapy when confronted with the combined use of agents that do not share similar pharmacodynamic targets. Although optimization of combination therapy may be possible by choosing the interval for one agent,⁸⁰ efficacy appears to be explained best when a combination of both pharmacodynamic properties is considered.^{79,162}

Reasonable models of a concentration-effect relationship have been proposed for numerous agents alone and in combination; however, optimal ratios remain to be defined for many drug-microbe combinations. Moreover, it is probably more complex than simply defining the optimal ratio for specific combinations. Even though one can define the best correlate, killing rates, in fact, may vary with the site of infection because penetration of a drug into or clearance from tissue varies from site to site. For example, logAUC proves to be the best predictor for clearance of organisms from the lung regardless of the dosing interval used. In contrast, given faster drug clearance from the thigh, the time above the MIC was a more important predictor of eradication when a longer dosing interval was used, whereas the logAUC was the best predictor of clearance of organisms with the use of shorter dosing intervals.¹³⁹ Similarly, in animal models of bacterial meningitis, greater kill rates were observed as time greater than MBC increased. However, when concentrations remained above the MBC for the entire dosing interval, which may not be unexpected in situations in which the antibiotic

half-life is longer in CSF than in plasma, kill rates were directly proportional to both peak/MBC and AUC/MBC ratios.¹⁵¹ These data suggest that we may need to expand the characterization of pharmacodynamic surrogates to look at the pharmacokinetic-pharmacodynamic interface at the site of infection rather than simply defining dosing strategies based on in vitro susceptibility data and the disposition characteristics of drugs in plasma. Without question, many data need to be collected and verified in the human host. The maximal dose and dosing regimen ideally are selected so that the resultant pharmacokinetic profile affords optimal pharmacodynamic activity without causing unnecessary adverse events, therapeutic failure, or both, as may be observed with inappropriate dosing. Development of a successful therapeutic strategy requires the following: incorporation of knowledge regarding the infecting pathogen; the physicochemical, pharmacologic, and pharmacokinetic properties of the anti-infective agent; and specific factors of the host or disease that are capable of altering either drug disposition or action. Such an approach enables the clinician to make clearer distinctions among agents with similar susceptibility profiles yet different mechanistic or pharmacokinetic profiles and to select an optimal drug regimen that will be most likely to result in successful therapy.

Effect of Suprainhibitory Antimicrobial Concentrations (Eagle Effect, Paradoxical Zone Phenomenon, Concentration Quenching)

In simplest terms, one typically thinks that anti-infective activity increases with increasing antimicrobial concentration. More sophisticated models describe increasing activity with increasing drug concentration to a maximal effect until activity reaches a plateau and remains relatively constant despite further increases in drug concentration (see Fig. 235.7). However, for many antibiotics, an increase in drug concentration can, in fact, result in a reduction in antimicrobial activity (Fig. 235.8).¹⁰¹ This paradoxical effect was observed as early as 1945 and described 3 years later by Eagle and Musselman, who reported the existence of antibiotic concentrations above the maximally effective concentration at which the killing rate of bacteria is paradoxically reduced.^{56,128} This phenomenon has been described with a host of organisms and although originally observed with penicillin has been confirmed with other β -lactams, glycopeptides, aminoglycosides, and fluoroquinolones.^{148,166,176,218,243} Given the diversity of agents that demonstrate a paradoxical reduction in activity with increasing drug concentration, this phenomenon probably cannot be explained by a single mechanism; and although they are not definitively elucidated, numerous mechanisms have been proposed to explain these observations.

For certain β -lactam antimicrobials, induction of β -lactamase may be responsible for the paradoxical effects observed in selected organisms. In vitro experiments performed with *Proteus vulgaris* suggested that

FIG. 235.8 Representative log-kill curve demonstrating the paradoxical effects that can be observed with suprainhibitory antimicrobial concentrations. MIC, Minimal inhibitory concentration. (Modified from Holm SE, Odenholdt-Tornqvist I, Cars O. Paradoxical effects of antibiotics. *Scand J Infect Dis Suppl.* 1991;74:113-117.)

the greatest paradoxical response seen with β -lactams was observed with agents that demonstrated the highest β -lactamase-inducing capacity and the poorest stability to degradation by this enzyme. When a mutant strain of this organism that was unable to induce β -lactamase production was evaluated, no paradoxical effect was noted.¹¹⁰ In animal models of peritoneal infection, antibiotics with strong dose-dependent induction of β -lactamase similarly demonstrated a paradoxical effect against β -lactamase-positive strains of *P. vulgaris*. However, no paradoxical effect was observed against β -lactamase-negative strains. Agents that were only weak inducers of β -lactamase demonstrated no evidence of a paradoxical effect, regardless of whether the *P. vulgaris* strains produced β -lactamase.¹⁰⁸

Because this paradoxical effect can be demonstrated with the β -lactams against organisms that do not produce β -lactamase, other mechanisms must also be responsible. One such mechanism may involve dysregulation of the bacterial autolytic system, which often confers tolerance to an organism but also may uncover an Eagle-type effect.⁹⁵ A paradoxical reduction in antimicrobial activity at high doses may be related to differences in regulation or expression of these autolytic enzymes. In *Enterococcus* strains that fully express only one of two recognized autolytic enzymes, diminished or deficient production of the second enzyme resulted in a paradoxical response to penicillin. Strains in which both enzymes were produced remained susceptible to the antibiotic irrespective of concentration, thus suggesting that a proportional dose-response relationship may require the synergistic activity of both enzymes.^{66,67} Further investigation into the paradoxical effect observed in tolerant organisms suggests that organisms in the exponential growth phase demonstrate this response more consistently than do those in the stationary phase.^{177,179} Animal models of *Staphylococcus aureus* endocarditis provide in vivo confirmation of the paradoxical response observed with tolerant organisms in vitro. Administration of continuous-infusion cloxacillin to animals infected with a nontolerant strain produced a dose-proportional reduction in bacterial density (\log_{10} CFUs/g) within the vegetation, whereas animals infected with a tolerant strain demonstrated a reduction and subsequent paradoxical increase in bacterial density with increasing dose. No statistical difference was observed in bacterial density within other organs or in overall survival, which raises questions regarding the in vivo significance of these observations.²³⁵

For antibiotics that demonstrate polyfunctional activity at supratherapeutic concentrations, a paradoxical response may occur as a result of secondary alterations in cellular functions that are requisite for antimicrobial activity. Despite a principal mechanism of action for the fluoroquinolones at the site of DNA gyrase, these agents appear to be bactericidal only in cells able to synthesize protein. As quinolone concentrations increase above those that are bactericidal, RNA synthesis and therefore protein synthesis are progressively inhibited, thus explaining the reduced rate of bactericidal activity observed at high quinolone concentrations.¹⁸⁸ Incompletely characterized genetic modifications also may confer a paradoxical response to antibiotics. β -Lactam resistance in methicillin-resistant *S. aureus* (MRSA) is mediated by de-repressing the production of a low-affinity PBP. However, because the modified PBP serves as an inefficient transpeptidase, it is regarded as an internal selective pressure in the bacterium, and a counter-mutation has arisen. Although it is not completely understood, the phenotypic expression of this counter-mutation is manifested as an Eagle-type resistance to methicillin.^{129,196} Finally, an observed paradoxical response may not be a result of the drug-microbe combination alone but a result of the chemical environment as well. A paradoxical effect with penicillin, in which both cell count and the rate of killing were affected, was demonstrated in *Streptococcus agalactiae* when the pH was reduced under in vitro conditions.¹⁰⁹

Most studies investigating the Eagle effect have been conducted in vitro, and the clinical implications of the paradoxical phenomenon have yet to be fully elucidated. However, anecdotal evidence appears to suggest that the clinical efficacy of antimicrobial agents can be compromised by high-dose antibiotic therapy. Case reports of β -lactam-susceptible streptococcal endocarditis and staphylococcal pneumonia describe patients who failed to respond to high-dose β -lactam therapy (plasma concentrations >100 times the MIC in one case), with subsequent

improvement in each case when the dose was lowered.^{77,88,221} For many agents, it is clearly advantageous to establish high peak drug concentrations early, the benefits of which include increasing log kill, preventing the selection of resistant mutants, overcoming refractoriness, and enhancing penetration of tissue. However, the relative safety of many drug classes (e.g., the β -lactams) often results in the use of doses that may be higher than necessary. When clear evidence is lacking for enhanced bactericidal activity at higher concentrations and the potential for diminished efficacy exists, escalation of antibiotic doses should be considered judiciously.

Effects of Subinhibitory Antimicrobial Concentration

Individuals may be exposed to subtherapeutic antimicrobial concentrations for many reasons, including underdosing, poor compliance, and, perhaps most commonly, the inability of the pharmacokinetic profile of the agent in question to afford adequate penetration to the site of infection. Exposure of bacteria to antibiotic concentrations below the MIC can have variable effects, depending on the organism and the antimicrobial agent. In fact, the effects observed with subinhibitory levels are not simply a milder extension of those observed at inhibitory concentrations but, instead, are qualitatively different from the effects observed at concentrations that equal or exceed the MIC.¹⁴⁴ Subinhibitory concentrations can have the following effects: enhance or impair opsonization and phagocytosis; affect the virulence of the bacteria by modifying the bacterial cell surface; alter adherence properties, antigen expression, or the excretion of enzymes and toxins (or any combination of these effects); and inhibit bacterial growth.^{168,169,226} The result can be an increase or decrease in responsiveness to therapy, both of which are discussed later in this section. Before reviewing the current data, however, one should note that this discussion does not refer to subinhibitory concentrations occurring after initial suprainhibitory drug levels. These particular effects are distinguished as PAE and are addressed separately.

Even though antibiotic concentrations may fail to reach or exceed the MIC, these agents still can affect the growth of an invading organism adversely.^{144,145,147} In fact, the term *minimal antibacterial concentration* (MAC), usually a fraction of the MIC, was coined to describe the lowest concentration of antibiotic required to produce either structural changes in the bacterium, a 1 \log_{10} decrease in the number of organisms present, or a 10% delay in turbidimetric growth in vitro.^{75,217} Rather than resulting in treatment failure, subinhibitory antimicrobial concentrations in concert with defenses in an immunocompetent host may be sufficient to clear the infection.²²⁶ Many effects have been observed to occur as a result of exposure to subinhibitory antimicrobial concentrations, and they are mediated by a variable number of mechanisms.

Increased susceptibility to phagocytosis may be seen with subinhibitory antibiotic concentrations and can occur in many ways. Subinhibitory concentrations may induce morphologic changes in the bacterium such that its size and shape are altered markedly, and, as a result, the immune system is signaled to clear the bacterium.^{13,217,236} However, subinhibitory concentrations of drugs that share a common intracellular target cannot be expected to have the same effects on bacterial morphology. Even though both penicillins and cephalosporins act through PBPs, subinhibitory concentrations of penicillins induce filaments in *Proteus mirabilis*, whereas cephalosporins induce the formation of globules.^{145,147,221} A likely explanation lies in their different affinity for the various PBPs, whereby they can be expected to bind selectively at low concentrations and rather nonspecifically at therapeutic or supratherapeutic concentrations. The preferential binding of ceftibuten to PBP-3 of *E. coli* at subinhibitory concentrations results in filamentation because this PBP allows crosswall but not sidewall synthesis.³⁰ Similarly, subinhibitory concentrations of the same drug applied to different organisms can produce different morphologic changes. In *S. aureus*, subinhibitory concentrations of loracarbef induce no morphologic changes, whereas similar concentrations lead to elongated forms and short-chain forms in *E. coli* and elongated and filamentous forms in *H. influenzae*.²²⁷

Although size may be one factor stimulating enhanced clearance of the organism, increased uptake by the immune system can be demonstrated even for cells with little gross morphologic alteration. Subinhibitory antibiotic concentrations can impair the synthesis of antiphagocytic

surface factors or liberate their release, thereby enhancing complement binding, opsonization, phagocytosis, and, ultimately, bacterial killing.^{97,103,135} Production of the antiphagocytic A protein of *S. aureus* can be repressed by subinhibitory concentrations of selected protein synthesis inhibitors and fluoroquinolones.^{154,210} Subinhibitory concentrations of β -lactam agents, but not vancomycin or protein synthesis inhibitors, increase the susceptibility of *S. agalactiae* to uptake by polymorphonuclear leukocytes (PMNs) because of the loss of antiphagocytic capsular material.¹⁰² Carbapenems and cephalosporins at subinhibitory concentrations increase the serum sensitivity of K1-positive *E. coli* by reducing expression of the K1 capsular polysaccharide.²¹⁹

Even drugs with no inherent bacteriostatic or bactericidal activity against a specific organism can induce sufficient changes in the cell surface to affect serum sensitivity. Preincubation of *P. aeruginosa* with subinhibitory concentrations of certain macrolides decreases cell surface hydrophobicity and enhances the sensitivity of the organism to human serum bactericidal activity.²²² Subinhibitory β -lactam concentrations are capable of sufficiently altering the peptidoglycan structure in MRSA to enhance susceptibility of the organism to the lysozyme present in sputum, even though the organism, because of altered PBP production, is no longer susceptible to the bactericidal activity of these agents.¹⁰⁷ Although most effects stimulating bacterial clearance by the host occur as a direct result of cellular changes in the organism, immune cells also can be altered by subinhibitory antibiotic concentrations. Erythromycin does not affect the generation of serum-derived leukoattractants, nor does it increase PMN cell numbers, yet it appears capable of stimulating the migration of PMNs. Researchers suggested that this effect probably results from the ability of erythromycin to sustain cellular migration by reducing the level of leukoattractant-induced autooxidation mediated by the myeloperoxidase–hydrogen peroxide–halide system.⁶³

In addition to enhancing bacterial clearance, subinhibitory antibiotic concentrations also can impair bacterial virulence mechanisms. For many organisms, pili, fimbriae, and fimbriae-associated adhesins are responsible for the initial events surrounding adherence and colonization at the site of entry or infection.¹⁹⁸ Subinhibitory quinolone and clindamycin concentrations are capable of decreasing the adherence of nosocomial pathogens (e.g., *Staphylococcus epidermidis*) to the synthetic materials of implantable catheters.^{35,206} Subinhibitory concentrations of penicillins, cephalosporins, azalides, and quinolones all have demonstrated the ability to decrease the formation of fimbriae or alter structures that mediate adherence. Specific examples include decreased adherence to oral and urinary tract epithelial cells for organisms such as *Porphyromonas gingivalis*, *E. coli*, *Salmonella typhimurium*, and *P. aeruginosa*.^{30,143,210,220,236} Moreover, these effects do not appear to be growth phase specific for select drug-microbe combinations.³¹

Subtherapeutic antibiotic concentrations also can have an impact on virulence by downregulating bacterial toxin production. Subinhibitory concentrations of clindamycin can inhibit toxin production in *S. epidermidis* markedly without appreciably altering bacterial growth.²⁰⁶ *Pseudomonas* exoenzymes that facilitate disease pathogenesis (e.g., exotoxin A, exoenzyme S, phospholipase C, total protease, elastase) are suppressed after exposure to subinhibitory concentrations of ciprofloxacin, tobramycin, and ceftazidime.⁸⁹ Finally, given the ability of subinhibitory fluoroquinolone concentrations to disrupt DNA structure sufficiently to interfere with effective mRNA production, continuous exposure of *S. aureus* to fluoroquinolones at subinhibitory concentrations decreases the production of nuclease and hemolytic α -toxin production.²¹⁰

Although discerning which of these effects, alone or in combination, are responsible for the subinhibitory effects is difficult, one may see in vivo that the impact of the sum total of these effects can be observed at the level of the host. In a nonneutropenic rat model of *Klebsiella pneumoniae* pneumonia, a continuous infusion of ceftazidime resulting in steady-state concentrations of 0.06 mg/L protected all the animals from death, despite an MIC for the pathogen of 0.2 mg/L. The same could not be said, however, for immunocompromised animals, which required steady-state concentrations of 0.38 mg/L for adequate protection.^{192,193} In a similar model of intraperitoneal *K. pneumoniae* infection, subinhibitory clindamycin concentrations resulted in an increase in bacterial clearance and a decrease in the log₁₀CFUs in blood at 72 hours.¹¹

In humans, low-dose ampicillin (such that concentrations in urine were no greater than one-fourth to one-half times the MIC), combined with large water intake, was demonstrated to clear documented *E. coli* urinary tract infection in 16 of 20 patients within 2 days of initiating therapy, whereas none of the 18 control subjects receiving the fluid intervention alone demonstrated resolution of the infection.¹⁸⁵ Despite the resistance of *Pseudomonas* in patients with cystic fibrosis, the fluoroquinolones remain capable of eliciting a significant reduction in sputum colony counts and improvement in clinical signs and symptoms.^{204,208}

Subinhibitory antimicrobial concentrations can be as potentially disadvantageous to the host as they can be beneficial. These concentrations can impair the ability of the host to respond to the bacterial inoculum, can augment bacterial defenses, and can serve to inactivate the antibiotic. For organisms that are susceptible to β -lactamase induction, strong inducers can upregulate β -lactamase synthesis at concentrations below the MIC. Although β -lactamase induction typically is a reversible phenomenon, many antibiotics demonstrate the ability to select out genetically de-repressed mutants at subinhibitory concentrations.^{205,214} Irrespective of whether this induction is phenotypic or genotypic, many antibiotics to which the organism originally may have been susceptible no longer retain their efficacy in light of β -lactamase production. This type of adaptive resistance, observed in response to sublethal antibiotic concentrations, also can be nonenzymatic. A single, one-time exposure of *P. aeruginosa* to subinhibitory concentrations of chlorhexidine results in unstable resistance, and repeated exposure leads to stable expression of altered cell surface macromolecules or efflux systems responsible for resistance.²²⁴ In a clinical strain of this same organism exposed to subinhibitory concentrations of fluoroquinolones and carbapenems for 5 days, a 16- to 32-fold increase in MIC was observed in concert with an alteration in overall protein expression.³⁶

Sublethal antibiotic concentrations also can stimulate the production of toxins that may be detrimental to the host. Exposure of enterohemorrhagic *E. coli* to subinhibitory concentrations of fluoroquinolones, cephalosporins, tetracyclines, and inhibitors of folic acid synthesis induces enhanced expression of a *Shiga*-like toxin (SLT-1), which is proposed to mediate events surrounding the development of hemolytic uremic syndrome. Subinhibitory fluoroquinolone concentrations also can stimulate the production of verotoxins in this same organism.^{237,244} Lincomycin and tetracycline at subinhibitory concentrations stimulate the production of heat-labile enterotoxin in enterotoxigenic *E. coli*, as well as *Vibrio cholerae* enterotoxin, even though these agents are principally protein synthesis inhibitors. Prior data suggest that the copy number of plasmids does not increase and proposed that the rate of enterotoxin liberation is enhanced as a result of antibiotic inhibition of the synthesis of proteins responsible for degrading the toxin.^{141,245} The α -toxin of *S. aureus* is demonstrated to be hemolytic, dermonecrotic, and antichemotactic and appears to be upregulated in the presence of subinhibitory nafcillin concentrations, irrespective of whether the isolate is susceptible to the agent. Greater hemolytic activity and increased lethality of the broth filtrate in a murine intraperitoneal model are observed, and this activity is ablated when incubated with anti- α -toxin antibody.¹²⁶ Other β -lactams (with the exception of aztreonam), ofloxacin, and trimethoprim are similarly capable of inducing α -toxin expression at subinhibitory concentrations.¹⁷⁰

The upregulation of protein expression by subinhibitory antibiotic concentrations not only is responsible for contributing to antibiotic and cellular destruction but also can enhance the binding of pathogens to host proteins and implantable devices. Subinhibitory concentrations of ciprofloxacin increase the transcription of fibronectin-binding proteins in *S. aureus* isolates and thereby result in greater adhesion to immobilized fibronectin and fibronectin-coated polymers, a particular concern with subcutaneously implanted devices that have polymer surfaces.^{23,24} Subinhibitory concentrations of antibiotic also can alter the immunogenicity of the pathogen such that the host can no longer mount the same degree of immune response. *S. aureus* isolates coincubated with subinhibitory concentrations of oxacillin demonstrated a diminished capacity to stimulate proinflammatory cytokine production (e.g., tumor necrosis factor- α , interleukin-1 β [IL-1 β], and IL-6) in human monocytes. Given that activation of the complement system and cytokine release are stimulated by peptidoglycan molecules of a certain size or tertiary

structure, subinhibitory β -lactam concentrations probably distort the peptidoglycan structure sufficiently that the immune system no longer effectively responds to these immunostimulatory components.²⁰³ The impact of subtherapeutic antimicrobial exposure has widely been examined in the agriculture industry because of the common use of antimicrobials for prophylaxis and growth promotion in livestock. With continuous administration of low, subtherapeutic antimicrobial doses, multiple mechanisms of bacterial resistance have been detected among exposed livestock.^{1,2}

Unless unusual circumstances prevail, the goal of therapy probably will not be to target plasma concentrations below the MIC. However, given the reality of encountering this situation in the clinical setting, practitioners certainly need to be aware of the potential implications for therapeutic response associated with subinhibitory concentrations of antimicrobial agents.

Effects That Persist After Antimicrobial Exposure (Postantibiotic Effect, Postantibiotic Leukocyte Enhancement, and Post- β -Lactamase Inhibitor Effect)

Early investigations into antibiotic activity described a delay in the recovery and regrowth of penicillin-exposed staphylococci and streptococci when the drug was removed by enzymatic inactivation or the organism was removed to drug-free media.^{22,52,174} In addition, in vivo evaluations of penicillin activity suggested that the effects of penicillin in an immunocompetent animal lasted well beyond the time when blood levels remained above quantifiable concentrations. Despite a half-life of minutes, many hours can elapse after the administration of a dose of penicillin before bacterial growth resumes.^{55,114,202} The term *postantibiotic effect* was coined to describe the suppression of bacterial growth that persists after brief exposure of the organism to an antimicrobial agent.³⁹ Unlike the subinhibitory effects discussed earlier in the chapter, the PAE occurs as a result of residual antimicrobial activity after initial exposure at inhibitory concentrations, as opposed to the subinhibitory concentrations themselves. The PAEs described to date typically are reversible; and although the mechanisms have not been elucidated fully, they probably are caused by either nonlethal damage or persistence of antibiotic at the site of action. In the same vein as the PAEs, the term *post- β -lactamase inhibitor effect* (PLIE) was coined to describe the residual effects of β -lactamase inhibitors after exposure to inhibitory concentrations.²²⁵ Similarly, one encounters the term *post-antibiotic leukocyte enhancement* (PALE), which is used to account for a PAE in vivo that lasts longer than that observed in vitro and is defined as exposure to subinhibitory concentrations of an antibiotic that render the organism more susceptible to the phagocytic and bactericidal action of neutrophils.

The PAE depends on many factors, the most discernible being the drug-microbe combination.¹¹² Since the initial descriptions with penicillin were reported, similar observations have been noted for a broad range of organisms, and essentially all antibiotic classes demonstrate a PAE against select organisms.³⁹ Virtually all agents evaluated demonstrate a PAE against susceptible gram-positive cocci. Inhibitors of protein and nucleic acid synthesis produce longer lasting PAEs in vitro than do cell wall-acting agents, with an average of 1 to 2 hours for β -lactams, 1 to 3 hours for fluoroquinolones, and 3 to 5 hours for protein synthesis inhibitors. For resistant gram-positive cocci, descriptions of a PAE are mixed. Against gram-negative bacilli, no appreciable PAE is observed for trimethoprim or the β -lactams in vitro, with the exception of the carbapenems, which demonstrate a PAE of 1 to 2 hours. The fluoroquinolones and protein synthesis inhibitors have PAEs of roughly 1 to 3 hours and 3 to 8 hours, respectively. Within this group of organisms, *P. aeruginosa* serves as an exception, and the fluoroquinolones and protein synthesis inhibitors display slightly shorter PAEs—1 to 2 hours and 2 to 3 hours on average for the respective drug classes. Similar observations have been described for the gram-negative anaerobes, with little or no PAE seen with the β -lactams but a measurable PAE observed for protein synthesis inhibitors.³⁹

Given that most drug classes demonstrate a PAE, multiple mechanisms must exist by which this effect arises. For the β -lactams, researchers proposed that the PAE corresponds to the time required for the organism

to synthesize new PBPs. The initial high β -lactam concentrations are thought to bind irreversibly to and thus inactivate the PBPs. As such, cell multiplication subsequently is prolonged until a critical number of PBPs are resynthesized and cell division can resume.²²⁶ Within the large class of β -lactam agents, however, further distinctions can be made based on the specific PBP bound and the subsequent morphologic alteration that is induced. Against *E. coli*, the longest lasting PAEs are observed for agents that induce the formation of spheroplasts and the shortest for agents that induce the formation of filaments. On drug removal, filaments (which may contain a biomass corresponding to more than 20 bacteria) readily separate into individual bacteria, whereas spheroplasts require a longer period to resynthesize a normal cell wall and resume replication.³⁴ Analogous to the β -lactams, the time required for the resynthesis or recovery of ribosomal proteins is probably responsible for the PAEs observed after the administration of an aminoglycoside. Evaluation of the intracellular events taking place in *E. coli* during aminoglycoside-induced PAEs suggests that both DNA and RNA synthesis resume immediately after drug removal; however, synthesis of structural and functional protein does not resume for nearly 5 hours.^{16,112} For the fluoroquinolones, the proposed mechanism behind the PAE is not as consistent with the antimicrobial activity of these agents. A progressive increase in ³H-thymidine incorporation in *S. aureus* during the PAE suggests that DNA synthesis continues to occur, and, thus, the PAE may represent the time needed to repair the damage to DNA gyrase, the time required to reestablish the function of DNA gyrase after dissociation of the antibiotic from the enzyme, or the time required to synthesize new DNA gyrase.⁸⁴

In addition to the specific drug-microbe combination, the magnitude and duration of drug exposure also have an impact on the PAE. Cell wall-acting agents (e.g., β -lactams and glycopeptides) demonstrate a concentration-dependent PAE. Increases in the concentration and duration of exposure (i.e., increasing AUC) prolong the PAE in both gram-positive and gram-negative organisms to a point of maximal effect, typically 2 to 6 hours, although the time may be shorter for some members of this class. In fact, the PAE appears to be related to the log-normalized AUC in a sigmoidal manner.^{38,94,131} Similarly, an increasing concentration of protein synthesis inhibitors is associated with progressive prolongation in PAE to a point of maximal effect. However, it can be difficult to establish with the aminoglycosides and fluoroquinolones because complete killing at supratherapeutic concentrations can obscure accurate determination of the PAE.^{39,112} Bacteriostatic agents generally demonstrate concentration-independent PAEs such that increasing the duration of antibiotic exposure, but not the concentration, results in an increase in PAE to some maximal effect.³⁹

As expected, the magnitude of the PAE also depends on whether antimicrobial agents are administered alone or in combination. Indifferent, additive, and synergistic PAEs all have been described with the use of combination therapy.^{72,90,112} However, for some drug-microbe combinations, the magnitude of the PAE may differ with the phenotypic expression of resistance. For *Enterococcus faecalis* isolates that demonstrate only low-level resistance to streptomycin or gentamicin, the effect of a penicillin-aminoglycoside combination on the PAE is markedly synergistic. In contrast, for isolates with high-level resistance to the aminoglycosides, no synergistic PAE is observed.²⁴¹ Additionally, physicochemical factors can affect in vitro determination of PAEs and, although the in vivo relevance is questionable, some are worthy of consideration. In *S. aureus*, the PAEs of penicillin and gentamicin are markedly protracted at the slightly acidic pH 6 compared with a physiologic pH of 7.4. Given that a relatively acidic pH can occur at the site of active infection, a disease-PAE interaction is possible. A similar pH-dependent effect on PAE is not observed with the fluoroquinolones or macrolides against *S. aureus*, nor is it noted for *E. coli* and *P. aeruginosa* with the β -lactams, fluoroquinolones, and macrolides.^{73,91} An increase in PAE in vitro also is observed as temperature drops, a finding that raises the question whether the PAE is truly altered or the generation time is lengthened. Regardless, the temperatures evaluated were much lower than physiologic temperatures and probably have no clinical impact in the presence of infection. Finally, anaerobic conditions are observed to increase the PAE for ciprofloxacin/*E. coli* and gentamicin/*S. aureus* combinations, but not with other combinations.⁷³

The attention paid to PAE of late highlights its significance, which lies in the flexibility that it affords to extend the dosing interval before redosing, essentially redosing, is necessary. Researchers suggested that agents with a small PAE require that a dosing interval be selected that will maintain concentrations above the MIC throughout most of the interval. Agents with a more protracted PAE can be given less often and thus at higher doses, thereby supporting the argument for once-daily dosing with drugs such as the aminoglycosides. However, many nuances can be identified between the in vitro conditions under which PAEs are determined and the in vivo conditions of infection such that the ultimate clinical (i.e., therapeutic) implications of these data have yet to be determined. In vitro, attempts are made to remove the drug completely (i.e., abruptly terminate drug exposure to the microbe) after initial exposure when determining the PAE. In contrast, drug concentrations fall in a more controlled, typically first-order fashion in vivo. The impact of this distinction on PAEs in patients remains unknown. Variable growth rates or metabolic states of the organism when growing in vivo similarly may have an impact on the PAE. In vitro, a prolonged PAE is observed when *Enterococcus faecium* is exposed to the combination of gentamicin and penicillin; yet, when the same drug concentrations and the same inoculum size are achieved in the vegetation of a murine aortic valve endocarditis model, no prolongation of PAE can be observed.⁹⁹ Similarly, a rat model of *P. aeruginosa* endocarditis failed to demonstrate a PAE in vivo for the combination of imipenem and gentamicin despite a PAE of nearly 5 hours determined in vitro; however, an observable PAE in vitro and in vivo was noted in the same model when ciprofloxacin was evaluated.^{98,111}

Impact of Inoculum Size on the Concentration-Effect Relationship

The antimicrobial effect observed at any given drug concentration may vary with the number of organisms at the site of infection. Accordingly, the size of the inoculum can be a primary determinant of drug efficacy. Early investigations clearly demonstrated that the duration of the infection before treatment is a significant predictor of clinical response.⁵¹ When therapy is delayed, presumably leading to a larger inoculum, the efficacy of that therapy often is affected adversely. In nonneutropenic rats, larger doses of antibiotic were needed to treat *K. pneumoniae*, whether administered by continuous or intermittent infusion, when the infection was allowed to progress 34 hours before therapy was initiated versus 5 hours.¹⁹² Many potential mechanisms have been proposed to account for this event. Large inocula perhaps generate a higher local density of enzymes that effectively reduce active (i.e., functional) antibiotic concentrations at the site of infection. Large bacterial populations also are statistically more likely to contain resistant organisms that arise by spontaneous mutation and predominate within the population as a result of the selective pressure posed by the antibiotic. One such example has been observed in a murine model of group A streptococcal myositis, in which the activity of penicillin is compromised most severely in the presence of a large inoculum (10^8 – 10^9 CFUs/mL), with relatively little impact on the activity of clindamycin. Given that the isolate did not produce β -lactamase and that any residual PAE was irrelevant because both regimens maintained drug concentrations above the MIC for the duration of the dosing interval, this effect of the inoculum was attributed in part to the selection of a cell wall-deficient mutant.²¹⁵ Clindamycin, however, is not devoid of susceptibility to the inoculum effect for all organisms; an increase in the size of the inoculum or an increase in the time until therapy resulted in a lower reduction in \log_{10} CFUs in a murine *Bacillus fragilis* abscess model.¹¹⁷ Another proposed mechanism for the effect of the inoculum lies in the finding that dense populations of organisms may grow at a slower rate or be metabolically inactive compared with their less dense counterparts. An effect arising by this mechanism probably will not affect antimicrobial agents that are bactericidal against both rapidly growing and stationary-phase organisms (e.g., fluoroquinolones). However, for agents that exert their bactericidal effects primarily on rapidly dividing organisms (e.g., β -lactams), activity may be compromised in the presence of an established infection in which the bacterial population is large and as many as 90% of the organisms may be slowly dividing and, thus, metabolically inactive. For clinical isolates of group G streptococci, time-kill studies

demonstrated rapid complete bacterial killing when the organism was primarily in log-phase growth, regardless of whether 10^4 or 10^7 organisms were involved. In contrast, when the organism was principally in the stationary phase, rapid and complete killing was observed only for the smaller inoculum (10^4 organisms), with no appreciable killing at 10^8 organisms. Furthermore, in patients with a protracted clinical course of infection or recalcitrant infection, therapy failed despite high drug doses and the presence of a susceptible isolate.¹³⁴

Attempting to link multiple pharmacodynamic effects in evaluating the outcome of anti-infective therapy poses an arduous task from both theoretical and practical perspectives, and, hence, a complete discussion is not undertaken in this chapter. Nonetheless, the combination of such effects has received some attention in the literature and merits mention. Specifically, large inocula appear to be capable of modulating the PAE and subinhibitory effects observed with numerous agents. Exposure of *E. coli* to subinhibitory sparfloxacin concentrations produced a pronounced inoculum-dependent subinhibitory effect. At a dose that was 0.3 times the MIC, growth of the organism was delayed by 0.3, 0.9, and 3.3 hours with inocula of 10^8 , 10^6 , and 10^4 CFUs, respectively, with similar observations noted for other drug-microbe combinations.^{38,167}

Concentration-Dependent Combination Effects (Synergy and Antagonism)

As discussed earlier and elsewhere in this text, antimicrobial combinations are used for many purposes: to prevent or delay the emergence of resistance, to enable dosage reduction and thereby minimize dose-related toxicities, and to treat polymicrobial infections. Combination therapy can be designed with the goal of synergistic or additive activity in mind, or, alternatively, these effects can occur without conscious consideration or forethought. Moreover, the undesirable outcomes of indifference or antagonism similarly can result through the combination of agents. Although a complete review of antagonism and synergy is beyond the scope of this section, we would be remiss not to mention concentration-dependent combination effects. We provide this brief discussion specifically to point out that a simple classification of drug combinations as synergistic, antagonist, and so forth is not always feasible. As discussed elsewhere, disagreement in the classification certainly can arise when different methods are used for evaluation.^{25,165}

However, even when restricted to evaluations using the same experimental methods, certain combinations can be classified differently, depending on antibiotic concentration. Synergy is observed with cefoperazone and low imipenem concentrations against MRSA; however, higher concentrations of imipenem antagonize the activity of cefoperazone. Although antagonism with imipenem often is explained away as being β -lactamase mediated, the concentration-dependent antagonism observed remains unexplained by this mechanism because antagonism was shown for strains that lacked β -lactamase production.¹⁸² The combination of penicillin and clindamycin at subinhibitory concentrations demonstrates synergy against group A β -hemolytic streptococci. At concentrations ranging from two to four times the MIC, the combination demonstrates antagonism, and at clinically relevant concentrations (≈ 100 times the MIC), indifference is observed, with the combination exhibiting no advantage over either agent alone.²¹⁶ Against isolates of vancomycin-intermediate *S. aureus*, antagonism is observed when methicillin and vancomycin are combined at subinhibitory concentrations. However, when the methicillin concentration exceeds the MIC, synergy is observed with the same combination. Although the mechanism behind this differential activity remains unclear, researchers proposed that the antagonism observed at lower methicillin concentrations results from an increase in the density of non-cross-linked D-alanyl-D-alanine side chains, the target site for vancomycin and a substrate for the PBPs. This increase would decrease the efficacy of methicillin as a PBP inhibitor by substrate competition.¹⁰⁴ For certain strains of methicillin-sensitive *S. aureus*, a combination of rifampin and methicillin below the MIC is synergistic, but above the MBC it is antagonistic. Similarly, a rifampin-vancomycin combination is synergistic at concentrations close to the MBC but indifferent as concentrations rise.²⁴⁸ Furthermore, for some drug-microbe combinations, it is not the classification per se that is affected by the concentration but rather the magnitude of the effect

observed. Against *E. faecium*, fixed piperacillin and variable teicoplanin concentrations are synergistic. However, the degree of synergy depends on the teicoplanin concentration; comparable synergistic activity occurs at teicoplanin concentrations of 2, 4, or 8 mg/L; reduced synergistic activity occurs at teicoplanin concentrations of 16 and 32 mg/L; and the greatest degree of synergy is observed at a concentration of 64 mg/L.¹⁸⁴

Thus the available data support the finding that, in many cases, the clinical assignment or “expectation” of synergy, additivity, or antagonism by specific combinations of antiinfective agents cannot be assumed simply by virtue of the drug class or drug-specific mechanisms of action, or both. With drug combinations for which the activity against an infecting pathogen is potentially concentration dependent, prediction of therapeutic outcome must entail some assessment, be it actual or theoretical (e.g., the use of pharmacokinetic modeling), of the time-dependent drug concentration profile at the site or sites of infection.

PHARMACOGENETIC-PHARMACOGENOMIC DETERMINANTS OF EFFECT

Although this chapter is designed to detail the pharmacokinetic and pharmacodynamic determinants of antiinfective drug response, we would be remiss not to introduce the emerging role of pharmacogenetics as a predictor of drug response and a driver of antiinfective drug therapy. Although the application of molecular biology to infectious diseases traditionally has been limited to diagnostics (e.g., polymerase chain reaction–based assays for the detection of viral pathogens and slow-growing microorganisms) and disease monitoring (e.g., viral loads), molecular tools increasingly are finding application with identifying the likelihood of drug response *a priori* and determining optimal treatment strategies for infectious pathogens. Genotyping strategies are used to identify mutations that confer drug resistance and guide the selection of antiretroviral therapy in management of human immunodeficiency virus infection.^{140,232} Similarly, viral genotyping appears to be among the most robust predictors of response to combination therapy in the treatment of hepatitis C virus,^{136,195} and it has prompted similar investigations for hepatitis B virus.^{92,124} Commercially available molecular-based assays have been developed for the determination of methicillin resistance in *S. aureus*, multidrug resistance in *Mycobacterium tuberculosis*, and vancomycin resistance in *Enterococcus* in clinical isolates. These methods appear to perform well compared with conventional phenotype-based methods,^{127,157,171} and the integration of these tools into clinical care has resulted in optimization of targeted antimicrobial therapy and improvement in patient care.^{15,62}

Currently, genetic testing is rarely indicated before initiation of antiinfectives. However, there are cases for which gene testing has proved to directly enhance the safety of prescribing. An abacavir black box warning for *HLA-B*5701* allele screening before drug initiation is recommended. This haplotype is commonly associated with idiosyncratic adverse drug reactions, with approximately 50% of those patients exposed to abacavir with the allele experiencing an adverse reaction compared with less than 5% without the allele.¹⁰⁵ Caution is also recommended when prescribing drugs (e.g., dapsone, nitrofurantoin, sulfasalazine) that could be affected by polymorphisms associated with glucose-6-phosphate 1-dehydrogenase (G6PD) variants because the enzyme is involved in protecting erythrocytes from oxidative stress and hemolysis can occur in those with enzyme deficiency; thus genetic testing should be considered if G6PD deficiency is suspected.²⁴⁶ Although the application of genotyping for specific enzymes related to the metabolism of antimicrobials is not routinely performed, in cases in which overall drug exposure is quite variable, genotyping has the potential to enhance dosing strategies. The antifungal agent voriconazole is case in point; CYP2C19 contributes to the metabolism of voriconazole, and poor CYP2C19 metabolizers have up to fourfold higher voriconazole levels compared with extensive metabolizers. Although CYP2C19 alone cannot explain variability in exposure, evaluation of CYP2C19 genotype can assist clinicians in the assessment of cases for which therapeutic concentrations of voriconazole cannot be achieved and guide dosing strategies.¹⁰⁰ The integration of genetic testing to optimize antimicrobial therapy will likely only continue to be used more commonly in the future as studies demonstrate clinical benefit.

CONCLUSION

With a recognized decline in the development of new antimicrobial therapies since the 1980s and the emergence of multidrug-resistant organisms (e.g., gram-negative organisms, *M. tuberculosis*), a continued need persists for the repurposing of older agents while awaiting the future development of newer therapies.²¹³ Unfortunately, there remains a relative paucity of pharmacokinetic-pharmacodynamic information for many of the currently available antimicrobial agents in children (e.g., antitubercular agents); and for older agents that continue to hold important places in pediatric therapeutics (e.g., metronidazole, clindamycin), complete profiles of their clinical pharmacology (i.e., absorption, biotransformation) in infants and children are lacking.⁸⁵ For both existing and emerging drug therapies, pharmacokinetics provides a powerful and valuable tool. The clinical scientist can use pharmacokinetics to characterize a given drug by providing a profile of its absorption, distribution, metabolism, and excretion in individuals with and without disease, during normal alterations of human physiology (e.g., pregnancy), as well as under conditions of normal altered organ function or body composition (e.g., growth and development, senescence). For the clinical practitioner, the tool of pharmacokinetics can provide a means to individualize drug therapy by characterizing the relationship between drug dose and resultant drug concentrations in plasma or other relevant biologic fluids (e.g., urine, CSF, synovial fluid, pleural fluid, peritoneal fluid). When linked with information regarding the pharmacodynamic behavior of the antibiotic, the susceptibility of the organism, and the status of the host, the application of pharmacokinetics affords the practitioner the ability to exercise some degree of adaptive control over drug therapy by selecting a drug and dosing regimen that have the greatest likelihood of producing both efficacy and safety.

Practicing Precision Medicine in Infectious Disease

For decades, practitioners who treat infectious diseases have had at their disposal specific, detailed information on most pathogens (e.g., in vitro sensitivity), antiinfective agents (e.g., killing characteristics, biopharmaceutical information, drug biotransformation, and pharmacokinetic data), and the host-infection interface (e.g., information regarding disease location, general physical condition of the patient, information pertaining to the intersection of development and disease). Consequently, the goal of “individualized therapy” has been the mantra of pediatric infectious disease. In the current genomic era, we can now quickly and relatively cheaply obtain genetic and genomic data about a patient and their pathogens that is not simply informative but also, in many cases, as illustrated previously, can be predictive. It is the synthesis of this information (much of which is presented in this chapter) and the application of tools such as pharmacokinetics that can reliably be used in an adaptive fashion to determine the proper antiinfective dose for a given patient and, most important, control the dose-exposure relationship that will enable the practice of true precision medicine in treating infectious diseases in infants, children, and adolescents.

Antibacterial Therapeutic Agents

Ruston S. Taylor • Debra L. Palazzi

This review of antibacterial agents is divided into two sections: (1) the clinical pharmacology of currently available antibacterial drugs and (2) the various aspects of administration of antimicrobial agents to infants and children. The second section includes dosage schedules and routes, prophylactic use of antibacterial agents, considerations in writing orders and prescriptions, and other aspects of administration. Other antimicrobial agents used for the treatment of viruses, fungi, mycobacteria, and parasites are discussed in other chapters dealing with these pathogens. For the most part, only antimicrobial agents approved for use in infants and children by the US Food and Drug Administration (FDA) are discussed, although promising new agents that are likely to be approved for use in pediatrics are mentioned where relevant.

CLINICAL PHARMACOLOGY

The antibacterial agents of value in treating infectious diseases in infants and children may be classified into three major groups:

1. Agents that target cell wall or cell membrane, including the following:
 - The β -lactams, including penicillins, cephalosporins, carbacephems, monobactams, and carbapenems
 - The glycopeptides (e.g., vancomycin)
 - The lipopeptides (e.g., daptomycin)
 - The polymyxin: colistin
2. Agents that interfere with protein synthesis, including the following:
 - Agents that bind the 30S subunit, including aminoglycosides, chloramphenicol, and tetracyclines
 - Agents that bind the 50S subunit, including macrolides, clindamycin, and linezolid
 - Other mechanisms: Rifamycins
3. Agents that target nucleic acids, including fluoroquinolones, sulfonamides, and metronidazole

The following properties that govern the use of each group of drugs in infants and children are considered: mechanism of action, mechanisms of resistance, in vitro activity, pharmacokinetics, indications for use, side effects, and toxicity.

AGENTS THAT TARGET THE CELL WALL

 β -Lactams

Biochemical Structure

The β -lactams are a large group of compounds that have in common a four-membered β -lactam ring. The subclasses of β -lactams differ from one another with regard to their side chains and the presence of other ring structures: the penicillins contain a five-membered thiazolidine β -ring fused to the β -lactam ring,¹⁹³ the cephalosporins have a six-membered dihydrothiazine instead of the thiazolidine ring, and the carbacephems have a methylene group replacing the sulfur atom in the dihydrothiazine ring of the cephalosporin nucleus. The β -lactam ring

is essential for antibacterial activity, whereas the side chains influence the pharmacologic properties of the β -lactam and the spectrum of antibacterial activity.

Mechanism of Action

Our understanding of the mechanism of action of the β -lactams has evolved over the past several decades. Researchers initially thought that binding of β -lactam to a bacterial cell membrane-associated enzyme (transpeptidase) blocked the terminal step in synthesis of the peptidoglycan layer of the bacterial cell wall. Cell death would ensue because the weakened cell wall could not withstand the osmotic and mechanical pressure resulting from a growing bacterium.³⁴⁹ Additional evidence suggested that it is a more complex process involving activation of endogenous autolytic systems^{249,351} and inhibition of bacterial enzymes called the penicillin binding proteins (PBPs), which include transpeptidase, carboxypeptidase, and endopeptidase. These enzymes are located beneath the cell wall and are responsible for cell wall synthesis by achieving cross-linkage between peptide chains of peptidoglycans. PBPs are vital for cell division, cell shape, and structural integrity. Because the specific PBPs within each bacterial species and the affinity of each β -lactam antibiotic for a particular PBP differ, some β -lactams have better activity than others against particular bacteria. The various β -lactam antibiotics can have different morphologic effects on the same bacterial species; this property is thought to be related to specific functions of the PBP to which the β -lactam binds.³³⁰ Some bacteria have a deficiency in the system of autolytic enzymes that results in inhibition, but not killing, of the bacteria by a β -lactam that otherwise would be bactericidal. This phenomenon is termed tolerance and is demonstrated in vitro by a minimal inhibitory concentration (MIC) in the susceptible range and a ratio of minimal bactericidal concentration (MBC) to MIC of 32 or greater.¹⁴⁷

β -Lactam antibiotics are bactericidal against most susceptible bacteria. The nature of the bactericidal activity has been described as time-dependent, as opposed to the concentration-dependent bactericidal activity of aminoglycosides.²¹¹ Bactericidal activity is thought to be optimal when the concentration of β -lactam antibiotic at the site of infection is 4 to 10 times greater than that of the MIC (or MBC) of the infecting organism. The rapidity and extent of killing are not increased when concentrations exceed that ratio. A more important determinant of bactericidal activity for β -lactams is the length of time during the dosing interval for which the concentration of antibiotic exceeds the MIC (time > MIC) for the infecting organism. Optimal bacterial killing correlates with time greater than MIC that exceeds 40% to 50% of the dosing interval.⁹¹

Penicillins

Although first discovered by Fleming in the late 1920s, penicillin G was not available for general use in the United States for another 20 years. Since that time, numerous semisynthetic penicillins have been developed. The penicillins can be classified into four groups (natural penicillins,

BOX 236.1 Microorganisms for Which Penicillin G or V Is the Drug of Choice

^aStrains that do not produce lactamase.

^bOnly those without altered penicillin binding proteins.

penicillinase-resistant penicillins, aminopenicillins, and extended-spectrum penicillins) based on their antimicrobial activity, with some overlap. The spectrum of activity among the compounds within each group usually is similar; the differences are attributable to their pharmacologic properties.

Natural Penicillins: Penicillin G and Penicillin V

Despite the more than 70 years that penicillin G has been in use, some bacteria continue to be exquisitely susceptible. Resistant strains of *Streptococcus pyogenes* (group A streptococcus) and *Streptococcus agalactiae* (group B streptococcus) have not emerged. Penicillin G remains the drug of choice for the treatment of disease caused by a wide variety of microorganisms (Box 236.1).

Most bacteria have acquired resistance to penicillin G by producing β -lactamases; resistance caused by altered PBPs occurs less commonly. Most strains of *Staphylococcus aureus* and *Staphylococcus epidermidis* produce penicillinase. *Neisseria gonorrhoeae* gradually developed resistance to penicillin G beginning in the late 1960s by various mechanisms, including plasmid-mediated production of a TEM1-like β -lactamase, as well as chromosomal mutations in at least four genes (*penA*, *penB*, *ponA*, and *mtrR*) that encode increased expression of an efflux pump and alterations in PBPs and porins.²⁷⁰ Mechanisms of β -lactam resistance in *Bacteroides* spp. and other gram-negative anaerobes include production of class A β -lactamases (penicillinase or cephalosporinase) and class B metallo- β -lactamases that hydrolyze carbapenems, as well as alteration of PBPs.²⁰ Historically, penicillin has been the antibiotic of choice for treatment of *Neisseria meningitidis* infections, but strains with reduced susceptibility to penicillin have been reported in Europe, South America, Asia, Australia, and less frequently in the United States, where approximately 15% of strains have alterations in PBP2 encoded by the *penA* gene that likely results from mosaic genes derived through transformation with DNA from commensal *Neisseria* spp. in the nasopharynx of colonized individuals. Although penicillin resistance resulting from production of β -lactamase has been reported, such strains are rare.¹⁷⁹

Of particular concern is the global dissemination of strains of *Streptococcus pneumoniae* resistant to penicillin G as a result of altered PBPs. Surveillance data in the United States estimated the average rate of penicillin nonsusceptibility to be 33% (high-level resistance, 16%), with the highest incidence of 44% reported in the south-central region.¹⁷³ However, with the introduction of the 7-valent pneumococcal conjugate vaccine (PCV7) in 2000, invasive pneumococcal disease in young children caused by vaccine serotypes decreased by approximately 90%. Conversely, invasive disease caused by nonvaccine serotypes increased.²⁰² The incidence of disease caused by 19A serotype increased, and these isolates are associated with β -lactam antibiotic resistance (including penicillin and third-generation cephalosporins).^{158,341} The Active Bacterial Core Surveillance (ABC) report from 2014 showed penicillin nonsusceptibility of 5.3% and cefotaxime nonsusceptibility of 3.3%.⁷⁰ From 1999 to 2003, approximately 6% of pneumococci were reported in the United States to exhibit a multidrug-resistance phenotype defined as resistance to penicillin, trimethoprim-sulfamethoxazole (TMP-SMX), erythromycin,

clindamycin, and tetracycline.¹⁷³ Although penicillin-resistant pneumococcal meningitis has developed in patients who were receiving vancomycin for pneumococcal sepsis,⁷⁸ no treatment failures have been documented when the appropriate dosage of vancomycin was administered. In 2010, the 13-valent pneumococcal vaccine (PCV13), which includes serotype 19A, replaced PCV7 in the United States. The introduction of PCV13 has resulted in a decrease in antibiotic-nonsusceptible invasive pneumococcal disease across all age groups, with the most dramatic reductions in children less than 5 years of age. Several antibiotic nonsusceptible serotypes have emerged following the introduction of PCV13, but no single nonvaccine serotype is predominant as was witnessed following the introduction of PCV7.³⁵²

In 2008, the Clinical and Laboratory Standards Institute (CLSI; formerly the National Committee for Clinical Laboratory Standards) published new *S. pneumoniae* breakpoints for penicillin because of a reevaluation showing that clinical response to penicillin was being preserved in clinical studies of pneumococcal infection, despite reduced susceptibility in vitro. Under the former criteria, susceptible, intermediate, and resistant MIC breakpoints for penicillin were less than 0.06, 0.12, and greater than 2 $\mu\text{g/mL}$, respectively, for all pneumococcal isolates, regardless of clinical syndrome or route of penicillin administration. Those breakpoints remain unchanged for patients without meningitis who can be treated with oral penicillin. However, for patients without meningitis who are treated with intravenous penicillin, the new breakpoints are less than 2, 4, and greater than/equal to 8 $\mu\text{g/mL}$, respectively. Furthermore, isolates from patients with meningitis are now categorized as either susceptible or resistant, with intravenous penicillin breakpoints of less than 0.06 or greater than 0.12 $\mu\text{g/mL}$, respectively. Use of narrow-spectrum agents, such as penicillin, is encouraged to prevent the spread of antimicrobial-resistant *S. pneumoniae* and also the spread of methicillin-resistant *S. aureus* and *Clostridium difficile*, which can result from use of broader spectrum antimicrobials.

Several oral and parenteral forms of penicillin G are available. Selection of a preparation is based on the pattern of antimicrobial activity, including the peak and duration of activity in serum and tissues, and factors that reflect absorption, distribution, and excretion of the drug. These characteristics of penicillins are as follows:

1. Aqueous (water-soluble) penicillin G produces high peak concentrations of antibacterial activity in serum within 30 minutes after intramuscular administration but is excreted rapidly; thus, the concentration in serum is low within 2 to 4 hours. If aqueous penicillin G is given by the intravenous route, the peak is higher and occurs earlier, and the duration of antibacterial activity in serum is shorter (≈ 2 hours). Aqueous penicillin G given intravenously is used for severe disease such as meningitis, complicated pneumonia, and endocarditis caused by susceptible pathogens. In such cases, the drug should be administered at frequent intervals, usually every 4 hours, until the infection has been controlled.
2. Procaine penicillin G given intramuscularly produces lower concentrations of serum antibacterial activity ($\approx 10\%$ to 30% of the peak concentration achieved by the same dosage of the aqueous form), but activity persists in serum for as long as 12 hours. Intramuscular administration of procaine penicillin G should be reserved for patients with mild-to-moderate disease who cannot tolerate oral preparations. A 10-day course of this agent may be used as an alternative to intravenously administered aqueous penicillin G for infants with documented or suspected congenital syphilis.³⁷⁰
3. Benzathine penicillin G given intramuscularly is a repository preparation that provides low concentrations of serum activity ($\approx 1\%$ to 2% of the peak concentration achieved by the same dosage of the aqueous form). After administration of this drug, concentrations of penicillin are measurable in serum for 3 weeks or more and in urine for several months. Pain at the site of injection is the major deterrent to widespread use of this unique antibiotic. A combination of the benzathine and procaine salts (900,000 and 300,000 U, respectively) is a less painful treatment and is comparable in efficacy to benzathine alone (1,200,000 U) for the treatment of streptococcal pharyngitis.²⁸ Benzathine penicillin G is appropriate for only highly susceptible organisms present in tissues that are well vascularized so that the drug can diffuse readily to the site of infection. Thus, benzathine

penicillin G is suitable for treatment of children with group A streptococcal pharyngitis or impetigo and for prophylaxis of streptococcal infection in children who have had rheumatic carditis. Current recommendations by the Centers for Disease Control and Prevention (CDC)³⁷⁰ for management of syphilis include the use of benzathine penicillin G for primary, secondary, and early latent syphilis (<1 year's duration). Benzathine penicillin G also is recommended for infants with suspected congenital syphilis who do not meet the criteria for therapy with a 10-day course of aqueous or procaine penicillin G and whose follow-up can be ensured for repeat serologic testing.

4. Oral preparations of buffered penicillin G (no longer available in the United States) and phenoxymethylpenicillin (penicillin V) are absorbed well from the gastrointestinal tract. The peak concentration of serum activity of penicillin V is approximately 40%, and that of buffered penicillin G is approximately 20% of the concentration achieved by the same dosage of aqueous penicillin G administered intramuscularly. Therefore, oral penicillins may be satisfactory for treating mild to moderately severe infections caused by susceptible organisms. Penicillin V and penicillin G have equivalent activity in vitro against gram-positive cocci, but penicillin V is less active than is penicillin G against *N. meningitidis*, *N. gonorrhoeae*, and susceptible strains of *Haemophilus influenzae*.¹⁹³ The benefit of treating streptococcal tonsillopharyngitis with a 10-day regimen of penicillin V for the prevention of acute rheumatic fever is based on indirect evidence derived from rates of pharyngeal eradication of *S. pyogenes* equivalent to those of injectable penicillin, the treatment with proven efficacy.^{100,320}

All penicillins are excreted by both glomerular filtration and tubular secretion. The concomitant use of probenecid, a drug that blocks tubular secretion of organic acids, and a penicillin can produce higher peaks and more sustained concentrations of antimicrobial activity. Dosages and dosing intervals may need adjustment when penicillins are administered to persons with altered renal function.

Penicillinase-Resistant Penicillins

The semisynthetic penicillinase-resistant penicillins (cloxacillin, dicloxacillin, methicillin, nafcillin, and oxacillin) were developed in response to the emergence of penicillinase-producing staphylococci. The acyl side chain, by means of steric hindrance, prevents hydrolysis of the β -lactam ring by penicillinases. Most strains of *S. aureus* produce penicillinase, regardless of whether the infection is health care-associated or community acquired. In areas of low rates of resistance to β -lactams, penicillinase-resistant penicillins are the β -lactams of choice for the initial management of patients with suspected staphylococcal disease. However, alternative effective antimicrobials should be substituted or added if endemic rates of antibiotic resistance exceed 10% to 15% or if the severity of the disease warrants empirical treatment of methicillin-resistant *S. aureus* (MRSA).¹³⁶ With the exception of methicillin, these agents are active against streptococci and can be used for empirical treatment of infections commonly caused by both staphylococci and streptococci. Because these agents are less active than penicillin G against streptococci, penicillin G should be used instead of these agents if streptococci alone are isolated from culture. Penicillinase-resistant penicillins have no activity against gram-negative bacteria or enterococci.²³²

Methicillin was the first penicillinase-resistant penicillin to be introduced and was available in parenteral form only. Oxacillin and nafcillin are available in both parenteral and oral preparations. Cloxacillin and dicloxacillin are available in oral forms only and are absorbed more efficiently from the gastrointestinal tract than the other oral drugs. Differences among these five penicillins include routes of elimination, degree of binding to proteins, degradation by β -lactamases, and in vitro susceptibility.²⁶² However, all are effective in the treatment of susceptible strains of staphylococcal isolates, and clinical studies have shown them to be equivalent when used at appropriate dosage schedules. Suspension formulations are poorly tolerated because of their unpleasant taste. Disease caused by methicillin-resistant staphylococci was reported shortly after introduction of the drug in the 1960s. Resistance is caused by alterations in PBPs, rather than production of β -lactamase. The *mecA* gene encodes a PBP2a that has low affinity for β -lactams, thereby resulting

in resistance to most β -lactam antibiotics currently available, including penicillinase-resistant penicillins, cephalosporins (first to fourth generation), and carbapenems. The mechanisms of resistance to other antibiotics are unrelated to PBPs and may be plasmid mediated or chromosomal.²²⁸ Coagulase-negative staphylococci, including *S. epidermidis*, are residents of the normal microbial flora of the skin and are occasional contaminants of body fluid cultures. These organisms can be pathogens in certain settings, such as in neonates, or in infections of prosthetic devices, such as heart valves or cerebrospinal fluid (CSF) shunts. Most strains of coagulase-negative staphylococci produce a penicillinase that inactivates penicillin G, penicillin V, and ampicillin, and many strains have *mecA*-mediated altered PBP2a, leading to methicillin resistance. In addition, these methicillin-resistant, coagulase-negative staphylococci frequently are resistant to cephalosporins, erythromycin, and clindamycin. Vancomycin is the drug of choice for pathogenic coagulase-negative staphylococci and severe disease known or suspected to be caused by MRSA. Some experts advocate the addition of nafcillin or oxacillin for empirical therapy for suspected MRSA until susceptibility results are known in patients who are severely ill, although toxicity may be increased with combination therapy.^{120,136}

Aminopenicillins

The aminopenicillins (ampicillin, amoxicillin, amoxicillin-clavulanate, and ampicillin-sulbactam) are semisynthetic β -lactam antibiotics formed by the addition of an amino group to benzylpenicillin. Amoxicillin differs from ampicillin by the presence of a hydroxyl group on the phenyl side chain. The aminopenicillins were the first penicillins that had activity against some gram-negative organisms, including *H. influenzae*, *Escherichia coli*, *Proteus mirabilis*, *Salmonella* spp., and *Shigella* spp., while retaining activity against penicillin-susceptible, gram-positive bacteria.²⁶¹

In contrast to penicillin G, aminopenicillins are significantly more active against *Listeria monocytogenes*; slightly more active against enterococci; equally active against *Actinomyces*, *N. meningitidis*, and clostridial and corynebacterial species; and slightly less active against group A streptococci, group B streptococci, and pneumococci. Aminopenicillins are the drugs of choice for the treatment of infections caused by *L. monocytogenes* and enterococci. Other organisms susceptible in vitro to ampicillin and amoxicillin include non-penicillinase-producing strains of *H. influenzae*, *Moraxella catarrhalis*, *N. gonorrhoeae*, *S. aureus*, *E. coli*, *Salmonella*, and *Shigella*. A survey of health care-associated and community-acquired *H. influenzae* and *M. catarrhalis* strains isolated from the blood and respiratory tracts of children in North America documented ampicillin resistance rates of 34% and 99%, respectively.¹⁷⁸ The in vitro spectrum of activity for amoxicillin and ampicillin is identical, except that amoxicillin is two times less active against *Shigella* and two to four times more active against enterococci and *Salmonella* than ampicillin.²⁶¹

As seen with penicillin G, the primary means of acquired resistance to aminopenicillins is the production of β -lactamase. However, organisms that are resistant to penicillin G or to methicillin because of altered PBPs—*S. pneumoniae* and *S. aureus*, respectively—also are resistant to aminopenicillins. β -Lactamase-negative, ampicillin-resistant strains of *H. influenzae* have been identified in the United States much less frequently than in Japan (0.2% vs. 2.6%, respectively).¹⁶⁵

The broad-spectrum bactericidal activity of ampicillin and amoxicillin provides the basis for the use of these drugs as empirical therapy for lower respiratory tract infections and acute otitis media, for which amoxicillin remains the drug of choice.¹¹ Ampicillin or penicillin G is the recommended initial empirical therapy in community-acquired pneumonia in a fully immunized infant or school-aged child admitted to a hospital ward if the local epidemiology reveals no substantial high-level resistance for invasive *S. pneumoniae*.⁵¹ Aminopenicillins are indicated for treatment of susceptible strains of *Shigella*-associated or *Salmonella*-associated enteric infections as well as susceptible acute and chronic infections of the urinary tract. By bacteriologic and clinical measures, amoxicillin is significantly less effective than ampicillin for the treatment of shigellosis.²⁵⁹

Both drugs are available for oral administration; ampicillin alone is available in a parenteral form. Amoxicillin provides higher and more

prolonged serum concentrations than those achieved with equivalent dosages of ampicillin; thus, amoxicillin can be given in lower dosage, two or three times per day, rather than four times, as required for ampicillin. An additional advantage of amoxicillin is that absorption is not altered when the antibiotic is administered with food, whereas absorption of ampicillin is decreased significantly when it is given with food. Ampicillin is associated more frequently with diarrhea than is amoxicillin.

β -Lactam- β -Lactamase Inhibitor Combinations

β -Lactamase inhibitors are compounds that have weak antibacterial activity but can bind irreversibly to the catalytic site of many β -lactamases and render them inactive. The inhibitors currently in use are clavulanic acid, sulbactam, and tazobactam, the last of which is halogenated penicillanic acid derivative. All three inhibitors are identical in their mode of activity but differ to some degree in their potency and spectrum of enzyme inhibition. These agents primarily inhibit the plasmid-encoded β -lactamases and less frequently the chromosomally encoded β -lactamases. β -Lactamase inhibitors have been formulated in a fixed ratio with a β -lactam antibiotic. The spectrum of activity of each combination is determined primarily by the spectrum of activity of the β -lactam. However, many determinants of the inhibitor influence its activity, including its affinity for the β -lactamase and its ability to traverse the gram-negative cell wall to bind to periplasmic β -lactamases.²¹⁷ From a clinical perspective, all three β -lactamase inhibitors are considered therapeutically equivalent. The β -lactamase inhibitors are most effective against *S. aureus*, *H. influenzae*, *M. catarrhalis*, *Bacteroides* spp., *E. coli*, and other Enterobacteriaceae. The main indication for the use of these combination antimicrobial agents is for the treatment of health care-associated infections or infections caused by susceptible β -lactamase-producing pathogens.

Amoxicillin-clavulanic acid. Amoxicillin combined with potassium clavulanate was introduced in 1984 for oral administration. The pharmacokinetic properties of the two drugs are similar; both are absorbed rapidly and are not affected when taken with meals. Gastrointestinal side effects, including nausea, vomiting, and diarrhea, occur more commonly with amoxicillin-clavulanate than with amoxicillin alone.¹⁹²

The combination drug is equivalent to amoxicillin alone in activity against amoxicillin-susceptible organisms. The addition of clavulanic acid extends the activity of amoxicillin to include β -lactamase-producing strains of *S. aureus* (but not methicillin-resistant strains), *H. influenzae*, *M. catarrhalis*, *N. gonorrhoeae*, *E. coli*, *Proteus*, *Klebsiella*, *Providencia*, *Haemophilus ducreyi*, and some anaerobic bacteria, including *B. fragilis*. Some β -lactamase-producing, gram-negative bacilli are resistant to amoxicillin-clavulanic acid because of either hyperproduction of β -lactamase or production of a β -lactamase that is not susceptible to clavulanate. Amoxicillin-clavulanate is not active against penicillin-resistant *S. pneumoniae* or vancomycin-resistant enterococci.

Amoxicillin is considered the preferred therapy for low-risk children with uncomplicated, mild to moderately severe disease of the respiratory tract, including initial empirical therapy for otitis media. In children who are at risk for penicillin-nonsusceptible pneumococcal acute otitis media, a 90-mg/kg daily regimen in two divided doses is recommended. Alternative therapy, including amoxicillin-clavulanic acid, should be considered if a β -lactamase-producing organism is known or suspected to be the cause of the disease based on risk factors, treatment experience, or microbiologic results. In 2001, high-dose amoxicillin-clavulanic acid suspension (Augmentin ES600; 600 mg of amoxicillin/5 mL and 42.9 mg of clavulanic acid/5 mL) was approved for use in children in the United States. The recommended dosage of this formulation is 90 mg/kg per day divided every 12 hours for the treatment of high-risk patients with acute otitis media.¹¹ The high ratio (14:1) of amoxicillin to clavulanate optimizes the amoxicillin dose without intensifying the risks for undesirable adverse effects associated with the β -lactamase inhibitor. The combination drug is useful in areas where the proportion of β -lactamase-producing strains of *H. influenzae* is large (40%) and *M. catarrhalis* organisms (most of which are β -lactamase producers) are identified more frequently as pathogens in otitis media, sinusitis, and other respiratory tract infections. Amoxicillin-clavulanate also has been used successfully for the oral treatment of urinary tract, skin, and soft

tissue infections, as well as for the treatment of human and animal bite wounds.⁶⁴

Ampicillin-sulbactam. Ampicillin combined with sulbactam as a parenteral β -lactam and β -lactamase inhibitor combination was approved in 1987. The spectrum of activity of ampicillin-sulbactam is similar to that of amoxicillin-clavulanate. It is most useful as monotherapy for potential polymicrobial intra-abdominal or gynecologic infections and is effective for treatment of soft tissue, urinary tract, and respiratory tract infections. Ampicillin-sulbactam has been shown to be safe and efficacious for the treatment of skin and skin structure infections caused by susceptible organisms in children aged 3 months to 12 years.²¹ The combination of ampicillin-sulbactam and an aminoglycoside has efficacy equivalent to that of a combination of ampicillin, clindamycin, and an aminoglycoside for empirical treatment of intra-abdominal infections in children.⁸⁵ Ampicillin-sulbactam is potentially useful for multidrug-resistant health care-associated infections caused by *Acinetobacter baumannii-calcoaceticus* complex.²⁵³ Carbapenems and third-generation cephalosporins are comparatively more active against members of the Enterobacteriaceae. Because ampicillin-sulbactam has no activity against certain strains of the Enterobacteriaceae that produce Bush group 1 β -lactamases and *P. aeruginosa*, it should not be used as empirical single-agent therapy for febrile neutropenic patients or severely ill patients with probable bacteremia.

Piperacillin-tazobactam. Piperacillin and piperacillin tazobactam, which are extended-spectrum penicillins, are semisynthetic derivatives of ampicillin that have better activity against gram-negative organisms because of a higher affinity for PBPs and greater penetration through the gram-negative outer membrane. Piperacillin combined with tazobactam was approved for use in adults in 1993 and was approved for pediatric use (2 months to 17 years of age) in the United States in 2007.³⁵³ It extends the spectrum of activity of piperacillin to include β -lactamase-producing strains of oxacillin-susceptible *S. aureus*, many members of the Enterobacteriaceae, and virtually all gram-positive and gram-negative anaerobes; its spectrum of activity is superior to that of ceftazidime and other β -lactam and β -lactamase inhibitor combinations. It has equivalent activity against gram-positive bacteria in contrast to ampicillin-sulbactam. Tazobactam, however, does not increase the activity of piperacillin against bacteria with resistance that is mediated by altered cell wall permeability to piperacillin, including certain strains of *P. aeruginosa*. Penicillin-resistant pneumococci, methicillin-resistant staphylococci, *Corynebacterium jeikeium*, most *Enterococcus faecium* strains, and most gram-negative bacteria that produce Bush group 1 β -lactamases (*Citrobacter*, *Enterobacter*, *Morganella*, certain strains of *Pseudomonas*, and *Serratia* spp.) are resistant to piperacillin-tazobactam.⁶⁴ Although studies have shown piperacillin-tazobactam to be safe and effective for the treatment of lower respiratory tract, intra-abdominal, pelvic, skin and skin structure, bone, and diabetes-related foot infections in adults, as well as for empirical treatment of febrile episodes in neutropenic adults,⁴⁹ there is less experience in children. It is a potentially useful agent that has been administered for the treatment of serious or complicated polymicrobial infections in children, especially in febrile neutropenic children, as initial empirical treatment. Piperacillin-tazobactam has been proposed as an alternative treatment to carbapenems for single-agent therapy in community-acquired intra-abdominal infections.³²⁹ Monte Carlo simulations have predicted achieving more time above the MIC₅₀ with prolonged infusions of piperacillin-tazobactam (i.e., 4 hours) in contrast to conventional dosing, for MIC range MIC 4 to 16 mg/L. Similar results have been observed with other β -lactams, including meropenem, doripenem, cefepime, and ceftazidime. Clinical studies have not been conclusive.²²⁹ Clinicians also should be aware that administration of piperacillin-tazobactam has been shown to cause false-positive *Aspergillus galactomannan* test results for up to 5 days after cessation of treatment¹⁹ but that newer formulations of piperacillin-tazobactam used in the United States are rarely associated with false-positive results.³⁶³

Adverse Effects and Sensitization

The penicillins are unique among antimicrobial agents in having little dose-related toxicity (Table 236.1). Seizures may occur under circumstances that result in high concentrations of penicillin in nervous tissue:

TABLE 236.1 Adverse Reactions to Penicillins

Type of Reaction	Frequency (%)	Most Frequent ^a
Electrolyte Disturbance		
Hyperkalemia, acute	Rare	PCN G
Gastrointestinal		
Diarrhea	2–5	Ampicillin
Enterocolitis	<1	Ampicillin
Hematologic		
Hemolytic anemia	Rare	PCN G
Neutropenia	1–4	PCN G, Naf, Ox, Pip
Hepatic		
Elevated AST	1–4	Ox, Naf
Neurologic		
Seizures	Rare	PCN G
Bizarre sensations	Rare	Procaine penicillin
Renal		
Interstitial nephritis	1–2	Methicillin
Hemorrhagic cystitis	Rare	Methicillin
Allergic		
IgE-mediated	0.004–0.4	PCN G
Cytotoxic antibody	Rare	PCN G
Immune complexes	Rare	PCN G
Delayed hypersensitivity	4–8	Ampicillin

AST, Aspartate transaminase; Naf, nafcillin; Ox, oxacillin; PCN G, penicillin G; Pip, piperacillin.
^aAll reactions can occur with any penicillin.

rapid intravenous infusion of single large doses, substantial dosages for prolonged periods in patients with impaired renal function, or high concentrations given by the intrathecal route. Confusion, dizziness, seizures, and psychosis caused by toxic concentrations of procaine have been associated with the administration of procaine penicillin G.³²⁴ Nephritis has been associated with the administration of some penicillins, most frequently after the use of methicillin. Bleeding because of drug-induced platelet aggregation has been noted after the administration of penicillin G.

Although toxicity may not be a significant concern with the penicillins, sensitization is an important factor.²¹⁴ Penicillins are haptens, that is, they are low-molecular-weight compounds too small to elicit an immune response alone, but when bound to a carrier molecule (e.g., host tissues or proteins), they are highly immunogenic in humans. The native penicillin molecule can bind to a protein, as can its major (benzylpenicilloyl) and minor (benzylpenicillin, benzylpenicilloate, benzylpenilloate) determinants. Four types of immune-mediated reactions can occur after the administration of a penicillin (or any drug or antigen): immediate hypersensitivity (immunoglobulin E [IgE]-mediated) reactions, cytotoxic antibody reactions, immune complex reactions (Arthus reaction), and delayed (cell-mediated) hypersensitivity reactions. Allergic reactions also can be classified as (1) immediate (onset ≤1 hour), accelerated (1–72 hours), or delayed (>72 hours). Researchers have estimated that an immediate serious reaction occurs in 2 per 10,000 courses, and fatal reactions occur in 1 per 100,000 treatment courses.^{30,347}

1. Type 1 immediate hypersensitivity reactions usually occur within 30 minutes after administration and are life-threatening events. The interaction of preformed mast cell-bound IgE antibody to the antigenic determinants of penicillin results in the release of mast cell mediators.⁴⁴ Clinical signs include hypotension or shock, urticaria, laryngeal edema, and bronchospasm. Acute anaphylaxis is a rare event after the administration of penicillin, but significant numbers of fatalities occur each year because of the extensive use of these drugs. Children are thought to have fewer systemic reactions than

do adults, presumably because of fewer previous exposures to penicillin antigens. Oral preparations are less likely to result in an immediate reaction than are parenteral forms, perhaps because antigens are altered in the gastrointestinal tract, absorption is slower, dosages are smaller, or a combination of these factors.

2. Type 2 cytotoxic antibody reactions can occur after passive absorption of the benzylpenicilloyl hapten by the membrane of circulating blood cells or by renal interstitial cells, especially when high dosages of penicillins are used for prolonged periods. IgM antibody, IgG antibody, or both antibodies to the benzylpenicilloyl antigen bind to the altered cell surface; complement can be activated, and damage to the cell ensues. Cytotoxic antibody reactions usually are manifested more than 72 hours after initiation of antibiotic therapy and include hemolytic anemia, leukopenia, thrombocytopenia, and drug-induced interstitial nephritis.
3. Type 3 immune complex (Arthus) reactions occur after the formation of immune complexes between soluble penicillin antigens and IgG and IgM antibodies. The complexes lodge in the skin, joints, kidneys, or other tissue sites. Complement activation occurs, and the clinical manifestations of serum sickness ensue—cutaneous symptoms (i.e., urticaria, maculopapular rash, and erythema multiforme), polyarthralgia, and fever. The onset typically is 7 to 21 days after initiation of penicillin therapy but can occur after use of the antibiotic has been discontinued. Although serum sickness has been associated with the administration of penicillins, it occurs more frequently after administration of cefaclor.
4. Type 4 delayed hypersensitivity reactions involve cellular rather than humoral immunity. On exposure to certain antibiotics, T lymphocytes become sensitized in a major histocompatibility restricted fashion and they mediate mild-to-severe reactions that include contact dermatitis, some maculopapular rashes, fixed drug eruption at sites of previous tinea infections, and toxic epidermal necrolysis. Diagnostic tools to detect an antibiotic that induces a type 4 reaction include the delayed reading (>6 hours) intradermal skin test, patch test, and in vitro lymphocyte transformation test. However, these tests have not been adequately standardized for routine use.³⁴⁷

Idiopathic reactions are those for which an immune-mediated mechanism has not been proved, but more recent data suggest that these reactions may represent a type 4 hypersensitivity reaction.³⁴⁷ Included in this category are the morbilliform exanthems, erythema multiforme, photosensitivity reactions, exfoliative dermatitis, and pruritus. Approximately 4% of courses of penicillin and up to 9% of courses of ampicillin or amoxicillin therapy are associated with a maculopapular rash. In some of these patients, the rash is a manifestation of a primary viral infection such as infectious mononucleosis, for which the penicillin was prescribed inappropriately.

Identifying patients who will have a significant reaction if penicillin is administered remains difficult. Serologic assays (radioallergosorbent tests) for the detection of IgE antibodies to major and minor penicillin determinants are available but are time consuming, expensive, and less sensitive than skin testing. Because the immediate reaction is mediated largely by IgE reagin or skin-sensitizing antibody, patients who are likely to respond subsequently with a life-threatening reaction can be identified by the use of intradermal tests with appropriate antigens. However, selecting the most appropriate antigens to be used for skin testing has been problematic because many different antigens may play roles in the allergic reaction. Penicillin is degraded to various clinical products. At least 10 metabolic breakdown products of the penicillin nucleus have been identified. Other potential antigens include macromolecular impurities present in solutions of the drug, high-molecular-weight penicillin polymers found in poorly buffered penicillin solutions standing for prolonged periods, side chains of the various penicillins, and the bacterial enzymes (amidases) used to prepare semisynthetic penicillins. Thus, investigators have had difficulty choosing sensitive and specific antigens to use for skin testing. When these products are used in penicillin skin testing, the predictive value of testing for drug-specific IgE antibodies is high. However, skin testing evaluates IgE-mediated allergy only. For antibiotics other than penicillin it is not clear if the appropriate antigenic determinants are being used, for which a negative test should be interpreted with caution.¹⁴¹

The most informative studies of skin test antigens have been those of Levine,²⁰⁹ who identified two antigens, benzylpenicilloyl poly-L-lysine (PrePen) and a “minor determinant mixture,” a preparation of a dilute solution of aqueous crystalline penicillin G that includes metabolic breakdown products. Only the PrePen reagent is available commercially in the United States. The CDC currently recommends the use of benzylpenicilloyl poly-L-lysine and, if available, a freshly prepared mixture of dilute minor determinant precursors, including benzylpenicillin G, benzylpenicilloate, and penicilloyl propylamine, as well as a positive control (histamine) and a negative control (usually glycerinated saline) after a protocol prepared by Beall.³⁰ Of the minor determinants, only benzylpenicillin G (penicillin G) is available commercially in the United States. For patients with immediate systemic reactions to amoxicillin or ampicillin (i.e., aminopenicillins), aminopenicillins should be included in the skin testing panel.

An epicutaneous (prick) test is performed first. If the patient's history of penicillin allergy is that of a mild reaction, the skin test reagent can be used at full strength; however, if the previous history is suggestive of anaphylaxis, a 1:100 dilution of the reagent should be used for the first prick test, followed by a full-strength test if no reaction with the diluted reagent occurs. If the prick test result is negative, an intradermal test is performed using duplicate 0.02 to 0.05 mL volumes of antigen solutions, and the skin is observed for 20 minutes. A positive result is indicated by a wheal-and-flare reaction that is more than 3 mm larger than the negative control; this result suggests a significant chance that a reaction will occur on subsequent administration of a penicillin. A negative result suggests that a significant allergic reaction will not take place. Although much effort has gone into clinical tests of these antigens, the predictive value of positive and negative results in children remains uncertain. Because of the risk for severe life-threatening reactions when a skin test is performed, having a physician present and resuscitation equipment and medications readily available is prudent.

At present, the physician must rely on the patient's history of an adverse reaction after administration of a penicillin to identify who is likely to be allergic. If the reaction appears to be related to the administration of a penicillin, the drug should be avoided for minor infections. More recent experience suggests that fewer than 10% of adults with a history of penicillin allergy have positive skin tests. Of those individuals with negative skin tests, IgE-mediated reactions occur in 4% or fewer if these patients receive penicillin, a rate that is similar to that in individuals with no history of penicillin allergy.³⁴⁷ Because no proved alternative therapies to penicillin are available for treating patients with neurosyphilis, congenital syphilis, or syphilis in pregnancy, the CDC recommends skin testing and desensitization of patients considered to have reacted positively to the skin test antigens.³⁷⁰ If a life-threatening infection should occur and penicillin is clearly the drug of choice, the physician may choose to administer the drug under carefully controlled conditions after desensitization. All penicillins are cross reactive with regard to sensitization; allergy to any one implies sensitization to all, although cross sensitivity is considerably less than 100%.

Cephalosporins

The cephalosporins have a broad range of activity that includes gram-positive cocci, gram-negative enteric bacilli, and anaerobic bacteria. Most cephalosporins are relatively resistant to hydrolysis by β -lactamases produced by *S. aureus*, but many are susceptible to gram-negative β -lactamases. Unlike other antimicrobial agents, this group has a high therapeutic-toxic index. For simplicity, the cephalosporins have been categorized as first-, second-, third-, fourth-, and fifth-generation agents (Table 236.2), based on the pattern of in vitro activity. Newer generation cephalosporins have been evaluated recently. Ceftaroline is approved by the FDA for the treatment of acute skin and soft tissue infections and community-acquired bacterial pneumonia in adults and children older than 2 months of age.

Pharmacokinetics

The cephalosporins are available as parenteral and oral products. Most of the parenteral drugs can be administered by the intravenous or intramuscular routes. Most of the oral products are absorbed well from the gastrointestinal tract. Esterification of the base compounds of

TABLE 236.2 Classification Scheme and Route for Cephalosporins

First Generation	Third Generation
Cefadroxil (PO)	Cefdinir (PO)
Cefazolin (IM, IV)	Cefditoren pivoxil (PO)
Cephalexin (PO)	Cefixime (PO)
Second Generation	Cefotaxime (IM, IV)
Cefaclor (PO)	Cefpodoxime proxetil (PO)
Cefoxitin (IM, IV)	Ceftazidime (IM, IV)
Cefotetan (IM, IV)	Ceftazidime/avibactam (IV)
Cefuroxime (IM, IV)	Ceftriaxone (IM, IV)
Cefuroxime axetil (PO)	Fourth Generation
Cefprozil (PO)	Cefepime (IM, IV)
Ceftibuten (PO)	Fifth Generation
	Ceftaroline (IV)

IM, Intramuscularly; IV, intravenously; PO, orally.

cefuroxime and cefpodoxime is required to enhance gastrointestinal absorption. The presence of food does not alter absorption and, for some antibiotics, even can enhance absorption. Cephalosporins penetrate most tissues and body fluids well, except CSF. The first- and second-generation cephalosporins do not achieve therapeutic CSF concentrations. CSF penetration of third-generation drugs varies but is generally adequate for most major meningeal pathogens, except cefotaxime/ceftriaxone-nonsusceptible pneumococci, for which vancomycin is added in the initial empirical regimen.¹⁹⁶ Cefepime, a fourth-generation cephalosporin, reaches adequate CSF concentrations for the treatment of most common invasive pathogens. There are no data regarding CSF penetration of ceftaroline, a fifth-generation cephalosporin. Because glomerular filtration and tubular secretion are the major modes of excretion, the urinary concentrations achieved are sufficient for the treatment of urinary tract infections. Ceftriaxone has dual excretion by the kidneys and the biliary tract and achieves high concentrations in urine and bile. The presence of moderate-to-severe renal insufficiency may require adjustment of the dosage or dosing interval for all cephalosporins, except those agents with biliary excretion. Hepatic insufficiency can affect the metabolism of cephalosporins that undergo biliary excretion; however, adjustments in ceftriaxone dosage or dosing interval are required only in the presence of both hepatic and renal insufficiency.

Therapeutic advantages of cephalosporins include concentration-independent bactericidal activity, broad-spectrum antibacterial activity, lack of significant dose-related toxicity, and relative stability against staphylococcal β -lactamases. Certain cautions must be kept in mind when prescribing cephalosporins: none is effective against enterococci, methicillin-resistant staphylococci (except ceftaroline), *L. monocytogenes*, chlamydial species, and *C. difficile*, and resistance may develop rapidly in closed communities, such as neonatal or pediatric intensive care units, because of inducible chromosomal β -lactamases produced by gram-negative bacteria. The new-generation cephalosporin ceftaroline has minimal activity against *Enterococcus faecalis* and no activity against *E. faecium*.^{32,331}

First-Generation Cephalosporins

First-generation cephalosporins are effective against gram-positive cocci, including β -lactamase-producing *S. aureus*, and they have variable activity against gram-negative enteric bacilli. Three first-generation cephalosporins currently are available for infants and children: the parenteral drug cefazolin and the oral products cephalexin and cefadroxil. Cephalothin is not available in the United States. Cefazolin produces higher concentrations in blood than previously available parenteral first-generation drugs. Cefadroxil can be administered in twice-daily doses because of its longer serum half-life. None of these agents will attain appreciable concentrations in the central nervous system (CNS).

These drugs are of value as alternatives to penicillin for disease caused by *S. aureus*, *S. pyogenes*, and susceptible *S. pneumoniae*, and they are active against some strains of community-acquired gram-negative

enteric bacilli such as *E. coli*, *P. mirabilis*, and *Klebsiella pneumoniae*. The oral preparations have comparable activity in vitro and in vivo. First-generation cephalosporins are valuable in children who have a history of nonanaphylactic allergy to penicillin. These drugs have been used to treat staphylococcal and streptococcal skin and skin structure infections, bone and joint infections, pharyngitis, and uncomplicated community-acquired urinary tract infections caused by susceptible bacteria. A meta-analysis revealed that many first-generation and other-generation cephalosporins (i.e., cephalixin, cefadroxil, cefuroxime, cefprozil, cefdinir, cefixime, cefpodoxime, and cefibuten) have equivalent or superior bacteriologic and clinical cure rates in contrast to penicillin for treatment of group A streptococcal pharyngotonsillitis.⁶⁸ Experts disagree on the significance of the results of this meta-analysis. Cefadroxil is effective for the treatment of streptococcal pharyngitis in a once-daily dosage schedule. Cephalixin has been used for sequential parenteral-oral treatment of staphylococcal osteomyelitis and arthritis occurring after surgical intervention and an initial period of parenteral antibiotic therapy. Cefazolin and cefuroxime are the antibiotics of choice for perioperative prophylaxis in selected surgical procedures.⁵⁶ Because first-generation cephalosporins have minimal, if any, activity against *H. influenzae* and *M. catarrhalis* and inadequate activity against penicillin-resistant *S. pneumoniae*, they should not be used for empirical treatment of respiratory tract infections. First-generation cephalosporins should not be used for empirical therapy of suspected severe gram-negative health care-associated infections; a third- or fourth-generation cephalosporin in combination with an aminoglycoside, or other classes of antibiotics, should be selected for this purpose.

Second-Generation Cephalosporins

The second-generation cephalosporins that are approved for use in children consist of one parenteral drug (cefuroxime) and three oral preparations (cefaclor, cefuroxime axetil, and cefprozil). Also classified with the second-generation cephalosporins are the cephamycins, of which only one, cefoxitin, is approved for use in children. When compared with the first-generation cephalosporins, the second-generation agents have similar or somewhat less activity against gram-positive cocci but better activity against *H. influenzae*, *M. catarrhalis*, *N. meningitidis*, *N. gonorrhoeae*, and some members of the Enterobacteriaceae. The cephamycins are more active than first- or other second-generation cephalosporins against gram-negative enteric bacteria and *B. fragilis*, but they have poor activity against gram-positive cocci.

Cefaclor. Cefaclor is more active than cephalixin against *H. influenzae*, *M. catarrhalis*, *E. coli*, and *P. mirabilis* and has activity against staphylococci similar to that of cephalixin. Cefaclor is an unstable compound and is destroyed within 2 hours in human plasma. It is susceptible in vitro to hydrolysis by the β -lactamases produced by approximately 40% of *H. influenzae* and nearly all *M. catarrhalis* isolates; presumed rates of resistance of *H. influenzae* are considerably higher when pharmacokinetic and pharmacodynamic parameters are taken into account.¹⁶⁵ Although cefaclor is effective therapy for susceptible bacteria causing otitis media, sinusitis, and mild-to-moderate cases of pneumonia, it is not the preferred empirical agent for these indications because it is not effective against penicillin-nonsusceptible strains of *S. pneumoniae*. The rare but potential risk for serum sickness, as well as the poor stability of this drug to some β -lactamases, has limited its use. The safety and efficacy of cefaclor have not been established for infants younger than 1 month of age, although the drug has been used successfully to treat neonatal otitis media.

Cefoxitin. Cefoxitin has excellent activity against anaerobic organisms and is the most active cephalosporin against *B. fragilis*.³⁴ It has selective activity against gram-negative enteric bacilli, but *Enterobacter* or *Pseudomonas* spp. are inherently resistant. Cefoxitin is resistant to hydrolysis by the β -lactamases produced by gram-positive bacteria and some of the gram-negative β -lactamases. Because it is a potent inducer of Bush group 1 chromosomal β -lactamases, its indiscriminate use should be avoided. Cefoxitin has been shown to be effective for infections involving facultative gram-negative bacilli and anaerobes, such as intra-abdominal, pelvic, and gynecologic infections. When combined with doxycycline, cefoxitin is effective for the treatment of pelvic inflammatory disease.³⁷⁰ The use of β -lactam and β -lactamase inhibitor combinations

or metronidazole, rather than cefoxitin, should be considered for empirical treatment of patients with life-threatening anaerobic infections because as many as 25% of *B. fragilis* strains can be resistant to cefoxitin.⁵ Higher doses of cefoxitin have been associated with an increased incidence of eosinophilia and elevated aspartate transaminase (AST) concentration. A diminished zone of inhibition in cefoxitin disk diffusion assays is useful in the clinical microbiology laboratory to detect inducible or constitutive (stably derepressed) AmpC Bush group 1 β -lactamase production among strains of *Citrobacter*, *Enterobacter*, *E. coli*, *Klebsiella*, *Morganella*, *Providencia*, *Pseudomonas*, and *Serratia*. Identification of this phenotype in vitro is important because these strains have high-level resistance to many classes of β -lactam antibiotics that may not be detected by standard susceptibility assays. Fourth-generation cephalosporins and carbapenems are potentially effective antimicrobial agents for these multidrug-resistant pathogens.¹⁷⁵

Cefprozil. Cefprozil has a structure similar to that of the first-generation cephalosporin cefadroxil. It is more active than the oral first-generation agents against *S. pyogenes*, *S. pneumoniae*, *Neisseria* spp., *H. influenzae*, *M. catarrhalis*, *E. coli*, *P. mirabilis*, *Klebsiella*, and, to a lesser extent, staphylococci. This drug is hydrolyzed by the β -lactamases produced by approximately 40% of *H. influenzae* and nearly all *M. catarrhalis* isolates; rates of resistance of *H. influenzae* are likely considerably higher when pharmacokinetic and pharmacodynamic parameters are taken into account.¹⁴⁸ The rate of resistance among all *S. pneumoniae* isolates in the United States is approximately 30%.¹⁴⁸ Because of its relatively long serum half-life, cefprozil can be administered twice daily. Cefprozil is comparable to penicillin, cefaclor, and erythromycin in the treatment of pharyngitis,²³⁵ and it is equivalent or superior to cefaclor and erythromycin in the treatment of mild-to-moderate skin and skin structure infections.²⁶⁵ Cefprozil is approved for the treatment of acute otitis media, mild lower respiratory tract infections, acute sinusitis, and skin and skin structure infections. However, it is not the preferred antibiotic for these indications because it is unlikely to be effective in children with penicillin-nonsusceptible *S. pneumoniae*, *H. influenzae*, or *M. catarrhalis*, on the basis of unfavorable pharmacodynamic parameters.³⁵⁴ Cefprozil is safe and effective as part of a parenteral-oral antibiotic regimen for the treatment of suppurative skeletal infections in children.³⁵⁵ The safety and efficacy of cefprozil have not been established for infants younger than 6 months of age.

Cefuroxime. In contrast to first-generation cephalosporins, this parenteral second-generation cephalosporin is slightly less active against staphylococci but is more active against group A streptococci, pneumococci, and many members of the Enterobacteriaceae. Its stability to β -lactamases is greater than that of first-generation agents, and it is the only first- or second-generation antibiotic that achieves substantial CSF concentrations. However, cefuroxime is not recommended for treatment of suspected or proved bacterial meningitis because of suboptimal CSF pharmacologic characteristics, particularly in the context of infections caused by *H. influenzae* or nonsusceptible *S. pneumoniae*, for which third-generation cephalosporins (cefotaxime and ceftriaxone) are indicated.³¹⁸ Cefuroxime has been approved for the treatment of skin and skin structure infections, lower respiratory tract infections, bone and joint infections, uncomplicated gonorrhea, and uncomplicated urinary tract infections caused by susceptible bacteria. Cefuroxime is most useful for the treatment of infections sufficiently severe to warrant parenteral therapy, in which susceptible *S. aureus*, *S. pneumoniae*, *S. pyogenes*, encapsulated or nonencapsulated *H. influenzae*, and *M. catarrhalis* are probable pathogens. Cefuroxime offers the advantage of single-drug therapy for these diseases. The safety and efficacy of cefuroxime have not been established for infants younger than 3 months of age.

Cefuroxime axetil. Cefuroxime axetil is an oral form of cefuroxime with a similar spectrum of activity. It is an ester prodrug of cefuroxime that is metabolized to the active drug by intestinal esterases. Oral absorption is increased by the presence of food. When crushed, the tablet has a bitter taste that renders it unpalatable. The suspension has an unpleasant flavor that makes it difficult for some children to tolerate and therefore may limit adherence. The drug may be considered a suitable alternative to amoxicillin for the treatment of otitis media¹¹ and sinusitis when coverage must include β -lactamase-producing bacteria. Cefuroxime

axetil has limited activity against penicillin-nonsusceptible pneumococci and *M. catarrhalis*, of which approximately 30% and 60%, respectively, of isolates are resistant.^{165,173} This agent has been approved for the treatment of uncomplicated urinary tract infection, skin and soft tissue infection, acute bacterial maxillary sinusitis, and lower respiratory tract infection caused by susceptible bacteria. Cefuroxime axetil is an effective alternative to doxycycline and amoxicillin for the treatment of early Lyme disease.³⁷¹ The safety and efficacy of cefuroxime axetil have not been established for infants younger than 3 months of age.

Third-Generation Cephalosporins

Third-generation cephalosporins approved for use in children include the parenteral agents cefotaxime, ceftriaxone, and ceftazidime and the oral agents cefixime, cefpodoxime proxetil, cefibuten, cefdinir, and cefditoren pivoxil. Third- and fourth-generation cephalosporins are the most potent cephalosporins against gram-negative enteric bacteria.¹⁷⁸ Most of these agents have excellent activity against *H. influenzae*, *M. catarrhalis*, *N. gonorrhoeae*, *N. meningitidis*, group A streptococci, and penicillin-susceptible pneumococci but relatively poor activity against staphylococci. Ceftazidime is the only third-generation cephalosporin, excluding the recently approved cephalosporin/β-lactamase combinations, with activity against *P. aeruginosa*. A serious global health concern has emerged because members of the Enterobacteriaceae have developed increased resistance to third-generation cephalosporins on the basis of plasmid-mediated production of extended-spectrum and AmpC β-lactamases.²⁷⁷ The parenteral cephalosporins provide high concentrations of drug in serum and adequate concentrations in CSF.

In 2010, the CLSI released revised breakpoints for Enterobacteriaceae for third-generation cephalosporins and the first-generation cefazolin. The current MIC breakpoints in micrograms per milliliter are 1 and less for susceptible, 2 for intermediate, and 4 and greater for resistant organisms for cefazolin, cefotaxime, and ceftriaxone. For ceftazidime the MIC breakpoints are 4 and less, 8, and 16 or greater for susceptible, intermediate, and resistant organisms, respectively. Similarly, breakpoints for aztreonam (a monobactam) were revised. The revised breakpoints seek to eliminate the need to perform an extended-spectrum β-lactamase (ESBL) screen to direct patient care.³⁶⁷

Cefotaxime. Cefotaxime has excellent activity against group A streptococci, susceptible pneumococci, *H. influenzae*, *N. meningitidis*, and *N. gonorrhoeae*. Because cefotaxime can be hydrolyzed by AmpC Bush group 1-inducible chromosomal β-lactamases and by ESBLs, it is not active against strains of Enterobacteriaceae that produce these β-lactamases. Cefotaxime is metabolized in the liver to desacetyl cefotaxime, a less active metabolite that may act synergistically with cefotaxime. Although it is metabolized in the liver, cefotaxime is excreted by the kidneys. High serum, tissue, and CSF concentrations of cefotaxime can be achieved at the recommended dosages. The rapid development of resistance by colonizing gram-negative enteric bacilli when cefotaxime was used extensively for initial treatment of neonatal sepsis raised concern that extensive use of newer cephalosporins in the nursery or intensive care units could lead to more rapid emergence of drug-resistant bacteria than had been identified with the traditional regimens of a penicillin and an aminoglycoside. Because of its broad spectrum of activity against many of the common pathogens causing pediatric infections, cefotaxime is used widely for inpatient treatment of lower respiratory tract infections, urinary tract infections, sepsis, intra-abdominal infections, bone and joint infections, and meningitis or ventriculitis caused by susceptible organisms. Studies in neonates have raised concern that when cefotaxime is used routinely as part of an empirical regimen for neonatal sepsis, colonizing gram-negative enteric bacilli can rapidly develop resistance and certain neonates have adverse outcomes.^{80,95} Therefore, it is prudent to reserve cefotaxime for appropriate clinical and microbiologic indications. In 2003, the CLSI published new breakpoints for defining the susceptibility of *S. pneumoniae* isolates to cefotaxime and ceftriaxone. The former breakpoints were based on attainable concentrations of these antibiotics in CSF and the level at which it was presumed that meningitis treatment failed because of elevated MICs. According to the former criteria, susceptible, intermediate, and resistant MIC breakpoints for cefotaxime and ceftriaxone were 0.5 μg/mL or less, 1 μg/mL, and 2 μg/mL or more, respectively, for pneumococci. Based on the newer

criteria, the original breakpoints should be used for isolates from CSF in patients with suspected meningitis, but isolates causing non-meningeal syndromes have breakpoints of 1 μg/mL or less, 2 μg/mL, and 4 μg/mL or more, respectively.⁷²

Ceftriaxone. The antibacterial spectrum of ceftriaxone is similar to that of cefotaxime, with activity against β-hemolytic streptococci (including groups A, B, C, F, and G), susceptible pneumococci, *H. influenzae*, *M. catarrhalis*, *Neisseria* spp., and many members of the Enterobacteriaceae. Surveillance data from pediatric patients in the United States revealed that no significant resistance has been reported against ceftriaxone among oxacillin-susceptible strains of *S. aureus*.¹⁷⁸ Nonetheless, this drug should not be used as empirical monotherapy for severe infections presumed to be caused by staphylococci, because it has minimal activity against MRSA and its efficacy for treatment of susceptible strains has not been established in children. Ceftriaxone is not active against most strains of *Pseudomonas*. It differs from cefotaxime in pharmacokinetic properties. Ceftriaxone undergoes extensive protein binding and has a long serum half-life. Because of its broad spectrum of activity against many of the pathogens that commonly cause sepsis, meningitis, and respiratory tract infections in older infants and children, along with its unique pharmacokinetic features, ceftriaxone has been used excessively for outpatient management of febrile infants and young children being evaluated for possible systemic bacterial infection. Whereas single-dose therapy was approved for the treatment of acute otitis media in 1997, a 3-day regimen is recommended as alternative therapy for patients with refractory cases caused by penicillin-resistant *S. pneumoniae*.^{11,207}

Ceftriaxone is effective for various sexually transmitted diseases (STDs), including chancroid, proctitis, epididymitis (in combination with doxycycline), and different forms of gonococcal disease (e.g., neonatal ophthalmia); uncomplicated urethral, endocervical, rectal, or pharyngeal gonorrhea (in combination with doxycycline for treatment of possible coexisting chlamydial infection); and disseminated gonococcal infection, meningitis, or endocarditis.³⁷⁰ Short-course ceftriaxone therapy for typhoid fever in children is comparable in effectiveness to chloramphenicol therapy.²⁴⁶ However, duration of ceftriaxone therapy longer than 5 days has been associated with fewer confirmed bacteriologic relapses.³³⁹ Ceftriaxone (or cefotaxime) is recommended for treatment of acute Lyme disease with advanced heart block (14 to 21 days) or meningitis (14 to 28 days).³⁷¹ Administering an aminoglycoside in addition to a third-generation cephalosporin to severely ill patients with suspected infection caused by gram-negative bacteria often is prudent pending culture data because of the risk for encountering plasmid-mediated ESBL resistance or inducing the expression of chromosomally mediated AmpC Bush group 1 β-lactamases.

For infections requiring prolonged therapy (e.g., suppurative arthritis, osteomyelitis, and brain abscess) and caused by susceptible organisms, ceftriaxone therapy is cost-effective for use outside of the hospital. Once the acute signs of disease have diminished and the child remains in the hospital for only parenteral therapy, discharge and daily administration of ceftriaxone in the home or clinic can be considered.

Because of its extensive protein binding, ceftriaxone can displace bilirubin from albumin-binding sites, with the potential risk for inducing kernicterus, although to date this adverse clinical effect has not been reported. Cefotaxime is administered to neonates more often than ceftriaxone because considerably more information is available on its safety and pharmacokinetics. Ceftriaxone is excreted and concentrated in bile. Gallbladder “sludge,” diagnosed by abdominal sonography (and not identifiable by other radiographic techniques), has been demonstrated in some patients who received ceftriaxone. The material appears to be a calcium-ceftriaxone complex and resolves on cessation of the drug. Most patients with ceftriaxone-associated sludge are asymptomatic, but occasionally patients have symptoms of gallbladder disease, and incidents of acute cholecystitis have been reported in a few children.

Ceftazidime. In contrast to cefotaxime and ceftriaxone, ceftazidime has poor antibacterial activity against *S. aureus*, is less active against penicillin-susceptible *S. pneumoniae*, and is slightly less active against group A streptococci, but it is more active against *P. aeruginosa*. It frequently is active in vitro against *P. aeruginosa* strains that are resistant to antipseudomonal penicillins. Resistance to ceftazidime can develop

in gram-negative bacteria by the production of ESBLs or because of decreased bacterial cell permeability, as seen with *P. aeruginosa*, *Acinetobacter*, and some *Serratia* strains. Ceftazidime is indicated for use in the following circumstances: infections suspected to be caused by *Pseudomonas*, including acute exacerbations of chronic pulmonary infections in patients with cystic fibrosis, chronic suppurative otitis media, or malignant otitis externa; thermal injuries; puncture wound infections of the foot; and complicated health care–associated infections.

Cefixime. Cefixime has a vinyl group instead of a chlorine atom at position 3 of the cephem nucleus and an aminothiazole oxime group, rather than a phenyl glycine side chain. These biochemical changes result in potent gram-negative activity. Cefixime was introduced in 1989 as an oral third-generation cephalosporin with a broad spectrum of activity, including activity against group A streptococci, *H. influenzae*, *M. catarrhalis*, susceptible *S. pneumoniae*, and many members of the Enterobacteriaceae, including *Shigella*, *Salmonella*, *E. coli*, *Klebsiella*, and *P. mirabilis*.²⁷ Cefixime, like ceftibuten, is distinguished from other extended-spectrum oral cephalosporins by its lack of activity against *S. aureus*. It also is inactive against *Citrobacter freundii*, *Enterobacter*, *P. aeruginosa*, and *Serratia*. Although cefixime has in vitro activity against penicillin-susceptible pneumococci, lower bacteriologic cure rates occurred with cefixime than with amoxicillin when cefixime was used to treat children with pneumococcal acute otitis media.¹⁵⁷ Cefixime is resistant to degradation by certain β -lactamases. Administration of cefixime is facilitated by once-daily dosing,¹¹² pleasant taste, and stability of the suspension at room temperature. Cefixime is effective therapy for uncomplicated urinary tract infections caused by *E. coli* or *P. mirabilis*, for shigellosis, and for acute otitis media or sinusitis caused by *H. influenzae* or *M. catarrhalis*.³⁹ Because of increasing minimum inhibitory concentrations required to inhibit growth of *N. gonorrhoeae*, the Centers for Disease Control and Prevention no longer recommend the routine use of cefixime for the treatment of gonococcal infections.³⁷⁰ Clinical studies indicate that the rate of laboratory-confirmed eradication of *Shigella sonnei* in an epidemic setting is higher with a 5-day than with a 2-day cefixime regimen,²³⁴ cefixime alone is equally effective as sequential therapy with intravenous and oral antibiotics in selected febrile infants with urinary tract infections,^{37,153} and a 14-day cefixime regimen for treatment of multidrug-resistant *Salmonella typhi* septicemia in children has efficacy comparable to that of a 5-day course of ceftriaxone therapy.¹³¹ Cefixime is not recommended for the treatment of infections frequently caused by staphylococci, such as skin or soft tissue infections, and it is not the most effective agent for the treatment of pneumococcal infections. The safety and efficacy of cefixime have not been established for infants younger than 6 months of age.

Cefpodoxime proxetil. The antibacterial activity of cefpodoxime proxetil is similar to that of cefixime, with the exception of improved activity against staphylococci. Cefpodoxime is active against group A streptococci; susceptible pneumococci; β -lactamase-producing strains of *N. gonorrhoeae*, *H. influenzae*, and *M. catarrhalis*; oxacillin-susceptible *S. aureus*; and many members of the Enterobacteriaceae. It is not active against *Enterobacter*, *Pseudomonas*, *Serratia*, or *Morganella*. Cefpodoxime proxetil, the ester prodrug of cefpodoxime, is cleaved by intestinal esterases to the active drug. Oral absorption is increased by the presence of food. Because of its longer serum half-life, cefpodoxime proxetil can be administered in twice-daily dosing intervals. Cefpodoxime is hydrolyzed by some ESBLs. The unfavorable palatability of cefpodoxime proxetil may adversely affect adherence.³³²

Treatment of group A streptococcal pharyngitis with a 5-day cefpodoxime proxetil regimen is equivalent to therapy with penicillin V and has been approved for this indication by the FDA.⁹³ A 5-day regimen is approved for the treatment of acute otitis media based on clinical outcomes that are comparable or superior to those with therapy with amoxicillin-clavulanate, cefaclor, or cefixime.⁸¹ Cefpodoxime is not likely to be effective for the treatment of acute otitis media caused by penicillin-nonsusceptible pneumococci because of its unfavorable pharmacodynamic parameters.³⁵⁹ It also has been approved for outpatient treatment of community-acquired respiratory tract infections, uncomplicated urinary tract infections, and mild skin and skin structure infections. The safety and efficacy of cefpodoxime proxetil have not been established for infants younger than 2 months of age.

Ceftibuten. Ceftibuten was approved by the FDA for pediatric use in 1995. The primary active component is formulated as a *cis*-isomer that is converted in serum to the less active *trans*-isomer. The chemical structure and spectrum of antimicrobial activity are similar to those of cefixime. Ceftibuten, like cefixime, is distinguished from other extended-spectrum oral cephalosporins by its lack of activity against *S. aureus*. Its antimicrobial activity against groups A, C, F, and G β -hemolytic streptococci is good, whereas its activity against groups B and D, as well as viridans streptococci, is poor. Ceftibuten exhibits MICs for penicillin-susceptible pneumococci in the susceptible range, whereas penicillin-nonsusceptible strains are ceftibuten-resistant. In contrast to other oral cephalosporins, ceftibuten is the most stable to hydrolysis by β -lactamases produced by Neisseriaceae, *Moraxella*, *Haemophilus*, and Enterobacteriaceae, including most strains of *E. coli* and *K. pneumoniae* that produce Ambler class A plasmid-mediated, ESBLs of the TEM, SHV, and OXA types. Ceftibuten is variably active against strains of *Citrobacter*, *Serratia*, and *Morganella*, but it is inactive against *Acinetobacter*, *Pseudomonas*, *Enterobacter*, *Bordetella*, and anaerobic species. It is also a weak inducer of AmpC Bush group 1 β -lactamases produced by *S. marcescens*, *E. cloacae*, and *Enterobacter aerogenes*.¹⁴²

Ceftibuten has excellent bioavailability and a favorable pharmacokinetic profile that facilitates a once-daily dosing schedule.²⁵ Treatment regimens of 10 days have been approved for streptococcal tonsillopharyngitis and acute otitis media caused by *H. influenzae*, *M. catarrhalis*, or *S. pyogenes* because of superior clinical and microbiologic efficacy data for ceftibuten in comparison with penicillin V in children with streptococcal tonsillopharyngitis²⁸⁰ and comparable clinical efficacy data for ceftibuten versus amoxicillin, amoxicillin-clavulanate, cefaclor, and cefprozil for the treatment of children with clinically defined acute otitis media with or without effusion. However, cumulative data from clinical trials indicate that microbiologic cure rates of pneumococcal otitis media are lower for ceftibuten than for comparable antimicrobial agents.¹⁴² Because of the increasing prevalence of nonsusceptible *S. pneumoniae* isolates, ceftibuten has almost no place in the treatment of acute otitis media, especially in young or otherwise at-risk infants and children.

Ceftibuten also should be considered as alternative therapy for sinusitis caused by susceptible organisms. Although not approved for this indication, ceftibuten achieved clinical success equivalent to and bacterial eradication superior to those reported with trimethoprim-sulfamethoxazole in the treatment of complicated or recurrent urinary tract infections in children.²⁴ Adverse reactions to ceftibuten, which are limited mainly to the gastrointestinal tract, occur in approximately 10% of children, a rate similar to comparable oral β -lactam antibiotics. The safety and efficacy of ceftibuten have not been established for infants younger than 6 months of age.

Cefdinir. Cefdinir was approved in 1999 for the treatment of acute otitis media in children. It has a broad spectrum of in vitro antimicrobial activity, favorable pharmacokinetics, a convenient once-daily or twice-daily dosage schedule, superior palatability, a low rate of adverse events, and proved clinical efficacy against common childhood pathogens.^{155,194} In contrast to cephalexin, cefaclor, cefuroxime, cefixime, and cefpodoxime, cefdinir has equivalent or superior MICs for groups A, B, C, F, and G streptococci, viridans streptococci, and oxacillin-susceptible staphylococci. Its in vitro activity against penicillin-susceptible and penicillin-nonsusceptible strains of *S. pneumoniae* is equivalent to that of cefuroxime and cefpodoxime but superior to that of other oral cephalosporins. Cefixime and cefpodoxime have superior activity against *H. influenzae* (including β -lactamase-producing strains), whereas cefdinir and cefuroxime have comparable activity against this pathogen. The activity of cefdinir against *M. catarrhalis* is similar to that of cefixime, cefpodoxime, and cefuroxime but superior to that of earlier-generation cephalosporins. Cefdinir is stable to hydrolysis by many common Enterobacteriaceae-produced β -lactamases. However, activity against these pathogens is variable. Cefdinir is inactive against strains of enterococci, methicillin-resistant staphylococci, *Legionella*, *Listeria*, *Acinetobacter*, *Citrobacter*, *Enterobacter*, *P. aeruginosa*, *Serratia*, *Stenotrophomonas*, and most anaerobes.¹⁴³

Based on comparative clinical and microbiologic efficacy trials, administration of cefdinir should be considered for children with (1)

acute bacterial otitis media caused by β -lactamase-positive or β -lactamase-negative strains of *H. influenzae* and *M. catarrhalis* or penicillin-susceptible strains of *S. pneumoniae* as either a 5- or 10-day regimen; cefdinir has efficacy equivalent to that of cefuroxime and cefpodoxime but superior palatability and therefore should be considered as an alternative to other second-line regimens; however, use of amoxicillin-clavulanate or three single daily doses of parenteral ceftriaxone is recommended if penicillin-nonsusceptible pneumococci are suspected or proved^{11,15,194}; (2) group A streptococcal tonsillopharyngitis in 5- or 10-day dosage schedules; (3) acute maxillary sinusitis caused by susceptible organisms; and (4) uncomplicated skin and skin structure infections caused by oxacillin-susceptible *S. aureus* or group A streptococci.¹⁷⁶ Although cefdinir is not approved for treatment of urinary tract infections, microbiologic data support its potential utility for community-acquired uncomplicated urinary infections.⁴⁶ The safety and efficacy of cefdinir have not been established for infants younger than 6 months of age.

Cefditoren pivoxil. Cefditoren pivoxil was approved by the FDA in 2002 for oral treatment of acute exacerbations of chronic bronchitis, pharyngitis, tonsillitis, and uncomplicated skin and soft tissue infections in adults and adolescents 12 years of age and older. Cefditoren is similar to cefdinir and cefpodoxime in its antibacterial activity. It is stable to hydrolysis by many common Enterobacteriaceae-produced β -lactamases. Cefditoren has the greatest in vitro antimicrobial activity of all oral cephalosporins against *S. pneumoniae*. The inactive metabolite pivalate is eliminated by the kidneys in combination with carnitine as pivaloyl-carnitine. Although cefditoren transiently decreases serum concentrations of carnitine, the clinical significance of this is not clear, but no adverse effects have been reported.²³³

Third-Generation Cephalosporin, β -Lactamase Combinations

Ceftazidime-avibactam. Ceftazidime-avibactam was approved by the FDA in 2015 for the treatment of complicated intra-abdominal infection and complicated urinary tract infection in adults who have limited or no alternative treatment options. Ceftazidime is a third-generation cephalosporin having activity against select gram-positive cocci and gram-negative bacilli, including *Pseudomonas aeruginosa*. Avibactam is a novel non- β -lactam, β -lactamase inhibitor exhibiting activity against Ambler class A (e.g., CTX-M, KPC, ESBL), C (e.g., FOX, AmpC), and select class D (e.g., OXA-48) β -lactamases. Ceftazidime-avibactam is available in a fixed 4:1 combination.^{203,373,379}

Mechanisms of action. As with other β -lactam antibiotics, ceftazidime exerts its bactericidal activity by binding with PBPs of susceptible bacteria, which results in inhibition of cell wall synthesis. Ceftazidime is distinct among third-generation cephalosporins because of its activity against *Pseudomonas aeruginosa*. This activity is secondary to distinct side chains attached at positions 3 and 7 of the cephem nucleus. Ceftazidime specifically inhibits PBP3 of gram-negative bacteria, which results in a compromised peptidoglycan cell wall, ultimately leading to bacterial lysis and death. Avibactam exerts inhibition by covalently acylating the active site, a serine residue, of susceptible β -lactamases. After initial acylation, slow deacylation has been shown to occur, which fully restores the activity of the five-membered urea ring for additional activity. This differs from existing β -lactamase inhibitors, as previous inhibitors bind irreversibly to substrate and are subsequently decomposed.^{203,373,379}

Mechanisms of resistance. Gram-negative bacteria demonstrate resistance to antimicrobial agents through numerous distinct resistance mechanisms, which can broadly be defined as either inherent or acquired. Organisms that possess or acquire β -lactamases classified as Ambler class B enzymes (e.g., NDM, VIM, IMP) and most OXA enzymes will exhibit resistance to avibactam. Resistance to avibactam, in combination with several different β -lactams, has also been shown to occur when (1) isolates of *P. aeruginosa* have decreased membrane permeability; (2) organisms have efflux pumps able to excrete antimicrobial agents after entry into the cell membrane; and (3) existing β -lactamases undergo point mutations resulting in resistant mutants with reduced inhibitor affinity. Avibactam has been reported not to induce expression of the chromosomal ampC in *Enterobacter cloacae*.^{203,373,379}

In vitro activity. Avibactam has been shown to restore the activity of ceftazidime against Enterobacteriaceae producing the most common

β -lactamases in US hospitals, which includes ESBLs and *Klebsiella pneumoniae* carbapenemases (KPCs).⁶⁹ Avibactam inhibits class A enzymes at least as well or better than clavulanate and tazobactam. The activity of avibactam against KPCs has been shown to be substantially greater than that of either clavulanate or tazobactam.³⁷⁹ Avibactam also inhibits class C enzymes but does not inhibit β -lactamases such as NDM, VIM, or IMP due to their lack of a serine residue at the active site.^{373,379} Sader and colleagues tested more than 10,000 clinically significant gram-negative bacilli, including Enterobacteriaceae, *Pseudomonas aeruginosa*, and *Acinetobacter* isolates, gathered from US hospitals and found that ceftazidime-avibactam had activity against ESBL producers (e.g., *Escherichia coli* and *Klebsiella pneumoniae*), *K. pneumoniae* not susceptible to meropenem, and *Enterobacter cloacae* not susceptible to ceftazidime alone. More than 95% of *P. aeruginosa* isolates were inhibited by ceftazidime-avibactam compared to an 80% susceptibility rate with meropenem, ceftazidime alone, and piperacillin-tazobactam. For ESBL-producing *K. pneumoniae*, greater than 99% were susceptible to ceftazidime-avibactam, whereas only 60% were susceptible to meropenem. *Acinetobacter* species, as with many other antibiotic agents, shows high resistance rates to ceftazidime-avibactam.³⁰⁵

Pharmacokinetics. Ceftazidime and avibactam each demonstrate nearly linear pharmacokinetics over a broad dosing range in adults; increases in dosage result in proportional increases in the peak plasma concentration. The pharmacokinetics associated with the concomitant administration of ceftazidime and avibactam do not result in altered pharmacokinetic profiles of either agent. Ceftazidime and avibactam each demonstrate low protein binding—21% for ceftazidime and 8% for avibactam—and are predominantly cleared by the kidney with a half-life of approximately 2.7 hours. The dosage should be reduced in adults with renal impairment. Although there are currently no labeled recommendations for patients receiving dialysis, both of these agents are efficiently cleared by hemodialysis; therefore, administration should occur after dialysis in patients with no alternative treatment options. Ceftazidime pharmacodynamic properties are optimized when the free drug concentration exceeds the MIC (%fT > MIC) of the target pathogen for approximately 40% to 50% of the dosing interval.³⁷³ Pharmacodynamic parameters appear to be best optimized for avibactam when the free inhibitor concentration is above threshold concentration (%fT > C_T), where the threshold concentration for both inhibitor and β -lactam is that which inhibits organism growth. The adult dosing recommendations are ceftazidime 2 g, avibactam 0.5 g as a 2-hour prolonged infusion every 8 hours.^{373,379}

Indications for use. During a phase II clinical trial for complicated intra-abdominal infection, ceftazidime-avibactam plus metronidazole demonstrated similar microbiologic and clinical response rates when compared to meropenem.²²⁴ Similarly, ceftazidime-avibactam recipients in a phase II clinical trial of patients with complicated urinary tract infection found the efficacy and safety of ceftazidime-avibactam was similar to the comparator, imipenem-cilastatin.³⁶¹ A phase III study comparing the safety and efficacy of ceftazidime-avibactam to doripenem in adults hospitalized for complicated urinary tract infection, including pyelonephritis, found ceftazidime-avibactam to be non-inferior to doripenem.³⁶⁵ Thus, the FDA approved ceftazidime-avibactam with available in vitro, in vivo, phase II trial data and preliminary phase III trial results for the treatment of complicated intra-abdominal infections, in combination with metronidazole, and complicated urinary tract infections, including pyelonephritis, in adults who have limited or no alternative treatment options.⁷⁴ Clinical trials are underway in pediatric patients.

Adverse effects. Data from phase I and II clinical trials indicate that ceftazidime-avibactam is generally well tolerated, with the rate of adverse and serious adverse events being similar between adult patients receiving ceftazidime-avibactam and those receiving comparator group agents.³⁷³ In a phase II trial for complicated intra-abdominal infection, the overall rate of adverse events was similar between groups receiving either ceftazidime-avibactam plus metronidazole or meropenem. However, patients in the ceftazidime-avibactam group did experience higher rates of nausea, vomiting, and abdominal pain.²²⁴ Additionally, a phase II trial for complicated urinary tract infection found that adverse drug event rates between patients randomized to

either ceftazidime-avibactam or imipenem-cilastatin were similar between groups. Of those patients receiving ceftazidime-avibactam, the most commonly reported adverse events included headache, gastrointestinal symptoms, and injection-site reactions.³⁶¹ Data currently suggest that the safety profile of ceftazidime-avibactam appears similar to that of ceftazidime alone.

Ceftolozane-tazobactam. Ceftolozane-tazobactam was approved by the FDA in 2014 for the treatment of complicated intra-abdominal infection and complicated urinary tract infection in adults. Ceftolozane is a novel third-generation cephalosporin with activity against select gram-positive and many gram-negative organisms, including potent activity against multidrug-resistant *Pseudomonas aeruginosa*.^{79,215,335} However, similar to other third-generation cephalosporins (e.g., ceftriaxone and ceftazidime), ceftolozane is vulnerable to attack by ESBLs and carbapenamases. Tazobactam, an established β -lactamase inhibitor, extends the spectrum of activity to include ESBLs and select anaerobes. Ceftolozane-tazobactam is available in a fixed 2:1 combination.^{79,333}

Mechanisms of action. Ceftolozane exhibits bactericidal activity through inhibition of PBPs, impairment of peptidoglycan cross-linking, aberrant cell wall synthesis, and finally the initiation of cell lysis. Ceftolozane has a chemical structure most similar to that of ceftazidime; however, the heavier side chain at position 3 of ceftolozane offers increased stability against AmpC β -lactamase production of *P. aeruginosa*. Tazobactam, a β -lactamase inhibitor, extends the spectrum of ceftolozane to include ESBLs and some anaerobes. Tazobactam stimulates ring opening at the active site of susceptible β -lactamases, resulting in the formation of an irreversible covalent bond between the β -lactamase and tazobactam, thereby inactivating the β -lactamase.^{79,306,333}

Mechanisms of resistance. Resistance mechanisms commonly used by *Pseudomonas aeruginosa* include use of efflux pumps, loss of cell wall porin proteins (OprD), and hyperproduction of efflux pumps and AmpC β -lactamases.^{250,335} Takeda and colleagues found that ceftolozane, in comparison to ceftazidime, demonstrated enhanced stability in the presence of AmpC β -lactamases. Further, ceftolozane activity is not hindered by the presence of efflux pumps or by loss of OprD, which are known to be primary resistance mechanisms used by *P. aeruginosa* against fluoroquinolone and carbapenem agents.^{333,335} In an effort to assess the propensity of ceftolozane to induce resistance in *P. aeruginosa* isolates, Takeda and colleagues performed serial passage experiments where ceftolozane demonstrated decreased rates of spontaneous mutation in *P. aeruginosa* isolates compared to that seen with ceftazidime, imipenem, and ciprofloxacin. Investigators suggest that resistance to ceftolozane is difficult to induce secondary to increased structural durability in the presence of AmpC β -lactamases. Ceftolozane activity is, however, hindered by organisms producing metallo- β -lactamases, carbapenemases, and ESBLs.^{215,333,335,340} The addition of tazobactam to this novel third-generation cephalosporin broadens coverage to include organisms producing ESBLs, a common resistance mechanism employed by many Enterobacteriaceae.^{333,335}

In vitro activity. Ceftolozane demonstrates a spectrum of activity similar to ceftazidime. It has select activity against gram-positive organisms, including streptococci, but less activity against staphylococci. It is active against gram-negative organisms, including drug-resistant isolates of *Pseudomonas aeruginosa* and Enterobacteriaceae.³³⁵ The addition of tazobactam, an irreversible inhibitor of β -lactamases, does not significantly impact the activity of ceftolozane against gram-positive cocci, but does extend the spectrum of ceftolozane to include select anaerobic organisms (i.e., *B. fragilis*)³²⁷ and gram-negative organisms producing ESBLs.^{215,333,340,377} It is important to note that tazobactam does not add significantly to the activity of ceftolozane against *P. aeruginosa*, as ESBL production is not a resistance mechanism commonly used by this organism. Farrell and colleagues analyzed the activity of ceftolozane/tazobactam against 7071 Enterobacteriaceae, with the most common pathogens being *Escherichia coli* and *Klebsiella pneumoniae*, and 1971 *Pseudomonas aeruginosa* isolates obtained from US hospitals.¹¹⁰ Of 2691 *E. coli* isolates, ceftolozane/tazobactam inhibited all non-ESBL-producing isolates at a MIC less than 2 $\mu\text{g/mL}$ and overall inhibited 99% of isolates, including ESBL producers, at a MIC less than 4 $\mu\text{g/mL}$. Similarly, non-ESBL-producing *K. pneumoniae* isolates were 100%

inhibited by ceftolozane/tazobactam at a MIC less than 2 $\mu\text{g/mL}$; however, decreased activity occurred in ESBL-phenotype *K. pneumoniae*, likely secondary to destruction of these agents by carbapenemase production. Although ceftolozane/tazobactam demonstrates overall good activity against Enterobacteriaceae, its anti-pseudomonal activity is most striking, as it is more potent than ceftazidime, cefepime, piperacillin/tazobactam, and meropenem. Importantly, ceftolozane/tazobactam retains potency even in the presence of multidrug and extensively drug-resistant *P. aeruginosa*.¹¹¹ Ceftolozane/tazobactam, as is the case with β -lactams, demonstrates poor activity against *Acinetobacter* spp. and *Stenotrophomonas maltophilia*.

Pharmacokinetics. In adults, ceftolozane and tazobactam each demonstrate nearly linear pharmacokinetics over broad dosing ranges; increases in dosage result in proportional increases in the peak plasma concentrations. The pharmacokinetics associated with concomitant administration of ceftolozane and tazobactam do not result in altered pharmacokinetic profiles of either agent. Ceftolozane and tazobactam demonstrate low protein binding at approximately 20% for ceftolozane and 30% for tazobactam. Ceftolozane is predominantly excreted unchanged in the urine with a half-life of 2.3 hours. Approximately 80% of tazobactam is excreted unchanged, the remaining 20% as an inactive metabolite into the urine.^{79,333,377} Because both ceftolozane and tazobactam are cleared primarily through renal filtration, dosage reductions are necessary when creatinine clearance is 50 mL/min or less. In patients receiving hemodialysis, ceftolozane/tazobactam should be administered upon completion of dialysis.³³³ For ceftolozane and ceftolozane/tazobactam, pharmacodynamic properties are optimized when the free drug concentration exceeds the MIC (%fT > MIC) of the target pathogen for approximately 40% to 50% of the dosing interval.⁷⁹ Adult ceftolozane/tazobactam dosing recommendations are ceftolozane 1 g–tazobactam 0.5 g administered via a 60-minute infusion every 8 hours.

Indications for use. In a phase III clinical trial for the treatment of complicated intra-abdominal infection in adults, ceftolozane/tazobactam plus metronidazole, even in the presence of multidrug-resistant pathogens, was found to be non-inferior to meropenem.³²⁸ Adverse events, most commonly nausea and diarrhea, were found to occur at similar rates between treatment arms. Ceftolozane/tazobactam also was found to be superior to high-dose levofloxacin in a phase III clinical trial for the treatment of complicated urinary-tract infections in adults, where more than 80% of the microbiologic modified intention-to-treat cohort (those with one or two uropathogens) had pyelonephritis.³⁶⁶ The frequency of adverse events, most commonly headache and gastrointestinal symptoms, was found to be similar between groups. With these data, ceftolozane/tazobactam received FDA approval for the treatment of complicated intra-abdominal infections in combination with metronidazole, and complicated urinary tract infections including pyelonephritis, in adult patients.³⁷⁵ Ceftolozane/tazobactam studies are underway to evaluate plasma pharmacokinetics and lung penetration in critically ill adult patients as well as a pharmacokinetic and safety evaluation in pediatric patients with proved or suspected gram-negative infection or for perioperative prophylaxis (NCT02387372 and NCT02266706). A phase III clinical trial is underway to evaluate the safety and efficacy of ceftolozane/tazobactam versus meropenem in the treatment of ventilated nosocomial pneumonia (NCT02070757), and a phase IV study is evaluating population pharmacokinetics and safety of this agent in adult patients with cystic fibrosis (NCT02421120).

Fourth-Generation Cephalosporins

Cefepime. Cefepime, the prototypic agent of this class of antibiotics, was approved by the FDA in 1996. It is distinguished from other cephalosporins by the rapid penetration of outer-membrane porins into the periplasmic space of gram-negative bacteria, facilitated by its net neutral charge; enhanced stability against hydrolysis by inducible or constitutively expressed chromosomally mediated AmpC Bush group 1 β -lactamases and Ambler class A plasmid-mediated SHV- and TEM-type ESBLs; and increased binding affinity to multiple PBPs. These factors contribute to cefepime's expanded spectrum of activity and improved efficacy against gram-negative pathogens in contrast to third-generation cephalosporins.

The *in vitro* activity of cefepime encompasses a broad range of gram-positive and gram-negative organisms, including oxacillin-susceptible staphylococci; approximately 75% of penicillin-resistant strains of *S. pneumoniae*; viridans streptococci; most strains of Enterobacteriaceae, including, most notably, ESBL-producing strains of *E. coli* and *K. pneumoniae*; and AmpC-mediated resistant *Enterobacter* spp. and *Citrobacter* spp., as well as approximately 90% of *P. aeruginosa* isolates. Furthermore, bacteria in which resistance to third-generation cephalosporins develops by means of single-step mutations usually remain susceptible to cefepime. Clinical and laboratory data also indicate that selection of cefepime resistance, specifically among *Enterobacter* spp. and *P. aeruginosa*, is uncommon. As with other cephalosporins, cefepime is inactive against enterococci, methicillin-resistant staphylococci, *S. maltophilia*, and many anaerobic organisms.^{178,189}

Cefepime is indicated for the parenteral treatment of lower respiratory tract, urinary tract, skin and skin structure, and intra-abdominal (in combination with anaerobic antibacterial agents) infections, as well as for empirical monotherapy in pediatric patients with cancer who have fever and neutropenia, for whom cefepime has been shown to be as effective as meropenem, piperacillin-tazobactam, or ceftazidime with or without an aminoglycoside. In comparative clinical and microbiologic efficacy trials, cefepime as a single antibacterial agent was equivalent to third-generation cephalosporins for the most common childhood pathogens. In addition, cefepime is as safe and well tolerated, as are other cephalosporin antibiotics.^{50,256,317}

Cefepime should be reserved for complicated community-acquired, health care-associated, or polymicrobial infections; penicillin-resistant and third-generation cephalosporin-resistant pathogens; and patients with cystic fibrosis and *P. aeruginosa* lung infections. Cefepime concentrations in CSF reach approximately 3 to 6 µg/mL (9% of the peak plasma concentration) in children with bacterial meningitis. Therefore, achievable CSF concentrations exceed the MICs of common CNS pathogens by at least 10-fold, except for penicillin- and cephalosporin-nonsusceptible *S. pneumoniae*.⁴³ Currently, data are insufficient to recommend cefepime as single-agent therapy for meningitis. The safety and efficacy of cefepime have not been established for neonates, but data extrapolated from pharmacokinetic studies among preterm and term infants support a dose of 30 mg/kg every 12 hours for infants younger than 14 days of age, regardless of gestational age. This dosage should provide antibiotic exposure equivalent to or greater than the approved dose of 50 mg/kg every 8 to 12 hours in older infants and children.⁶⁷

Fifth-Generation Cephalosporins

Ceftaroline. Ceftaroline fosamil is a prodrug that is rapidly biotransformed when administered intravenously to the active agent, ceftaroline. Ceftaroline is a broad-spectrum, advanced-generation cephalosporin initially approved by the FDA in 2010 for the treatment of community-acquired pneumonia and skin and skin structure infections in adult patients. This agent distinguishes itself from other cephalosporins with its activity against multiple gram-positive organisms known to exhibit resistance to existing β-lactam agents including *Streptococcus pneumoniae* as well as methicillin-resistant *S. aureus*, including those isolates found to be vancomycin-intermediate and resistant. Ceftaroline also has select activity against gram-negative organisms, including those prevalent in the respiratory tract (e.g., *M. catarrhalis* and *H. influenzae*), but has restricted activity against *P. aeruginosa* and exhibits instability in the presence of those organisms producing either extended-spectrum or AmpC-type β-lactamases.³³¹

Mechanisms of action. Similar to other β-lactam antibiotics, ceftaroline exerts its bactericidal activity by binding with PBPs of susceptible bacteria, which results in inhibition of cell wall synthesis. Ceftaroline has high affinity for PBPs 1, 2, and 3 for methicillin-susceptible strains of *S. aureus* (MSSA). However, this agent also contains a side chain with an alkoxyimino group in the C7 acyl moiety that provides *in vitro* activity for MRSA with high affinity for the PBP2a and another side chain with a 2-thiazolythio spacer group modification that optimizes the anti-MRSA activity. Because of its potent binding to PBP2x, ceftaroline also is active against *Streptococcus pneumoniae* resistant to penicillins and other cephalosporins.³³¹

Mechanisms of resistance. During *in vitro* single-step selection investigation, where the goal was to detect the frequency of mutation

occurrence, Mushtaq and colleagues failed to detect ceftaroline-resistant *S. aureus*, including isolates of MSSA, MRSA, vancomycin-intermediate *S. aureus* (VISA), or *S. pneumoniae*, regardless of penicillin susceptibility. Multistep selection investigation also was unable to detect isolates of mutant *S. aureus*.²⁵⁵ However, ceftaroline resistance has been described by Alm and colleagues, who identified four isolates of MRSA with MIC values greater than 2 mg/L from medical centers located in Thailand and Spain. They characterized ceftaroline resistance in isolates as occurring secondary to (1) mutations in PBP2a that resulted in decreased ceftaroline binding affinity, and (2) alterations in the non-penicillin-binding domain (nPBD), the dimerized portion, of PBP2a. Mutation in the nPBD portion of PBP2a weakens the dimerization between PBP2a and PBP2, which leads to binding of PBP2 with other proteins and ultimately allows cell wall production to occur.⁶ In addition to potent activity against multidrug-resistant gram-positive organisms, ceftaroline also demonstrates activity against many Enterobacteriaceae where the spectrum of activity of this agent resembles that of other extended-spectrum cephalosporins. Ceftaroline activity is, however, lost against those organisms producing extended-spectrum or AmpC-type β-lactamases.^{255,381}

In vitro activity. In addition to this agent's anti-MRSA activity, ceftaroline also retains activity against isolates with reduced susceptibility to vancomycin (glycopeptide-intermediate *S. aureus* [GISA], heterogeneous GISA [hGISA], and glycopeptide-resistant *S. aureus* [GRSA]) or linezolid.^{32,331} This antibiotic has *in vitro* activity against gram-positive organisms, including *S. aureus*, both MSSA and MRSA; coagulase-negative staphylococci; group A and group B β-hemolytic streptococci; and *S. pneumoniae*, including multidrug-resistant strains. It also has modest activity against *E. faecalis*. Ceftaroline has no activity against *E. faecium* (MIC₉₀ >1632 µg/mL). It has activity against penicillin-nonsusceptible viridans group streptococci. Ceftaroline is active against non-ESBL enteric gram-negative organisms, including *E. coli* and *K. pneumoniae*; respiratory gram-negative organisms (including *M. catarrhalis* and *H. influenzae* and β-lactamase-positive strains); and *N. gonorrhoeae*. It has limited activity against nonfermenting gram-negative organisms, including *P. aeruginosa* and *A. baumannii* (with MIC >16 mg/L for both). Ceftaroline can induce expression of AmpC β-lactamases in a degree similar to that of ceftriaxone and cefotaxime based on *in vitro* induction assays.³³¹

Pharmacokinetics. Ceftaroline fosamil is a prodrug that is converted into its active form by plasma phosphatases. Data from single- and multidose studies demonstrate nearly linear pharmacokinetics of ceftaroline over a broad dosing range; an increase in dosage results in proportional increases in peak plasma concentrations (C_{max}) and area under the concentration-time curve (AUC).^{288,381} Protein binding of this agent is minimal and was found to range from 1% to 19% over different concentrations. Ceftaroline and its inactive metabolite, ceftaroline-M-1, are eliminated predominantly via renal excretion with half-lives of 2.6 hours and 4.5 hours, respectively. Dosage adjustment is required for moderate renal impairment and for patients receiving hemodialysis. Optimal pharmacodynamic parameters, similar to other cephalosporins, are achieved when the free drug concentration exceeds the MIC (%fT > MIC) for 50% of the time interval for staphylococci and 60% of the time interval for gram-negative bacilli.^{288,381} Adult ceftaroline dosing recommendations are 600 mg administered via a 60-minute infusion every 12 hours.¹¹⁸ In 2016, ceftaroline was FDA approved for the treatment of community-acquired pneumonia and bacterial skin and skin structure infections in children.

Indications for use. In phase III clinical trials for the treatment of skin and skin structure infections, ceftaroline proved to be non-inferior to a combination of vancomycin and aztreonam with similar clinical cure and bacterial eradication rates.^{89,336} Two randomized, double-blind, multicenter, phase III trials showed similar cure rates when comparing ceftaroline and ceftriaxone (± clarithromycin) for the treatment of community-acquired pneumonia in adults.^{115,222} A phase II/III clinical trial evaluated the safety and efficacy of ceftaroline versus intravenous comparators (either vancomycin or cefazolin with the option to add aztreonam) for the treatment of acute bacterial skin and skin structure infections in pediatric patients 2 months to 17 years of age and found ceftaroline to be well tolerated and as effective as the comparator

regimens.¹⁹⁸ In a phase II/III clinical trial evaluating the safety, tolerability, and effectiveness of ceftaroline versus ceftriaxone in pediatric patients between the ages of 2 months and 18 years with community-acquired pneumonia, ceftaroline was found to be well tolerated, with similar rates of adverse events between groups, and as effective as ceftriaxone.⁶⁵ Ceftaroline is dosed at 8 mg/kg every 8 hours in children 2 months to less than 2 years of age; at 12 mg/kg every 8 hours in children weighing less than 33 kg and more than 2 years of age; and at 400 mg every 8 hours in those weighing more than 33 kg.^{65,198} Higher doses were used in a phase IV clinical trial evaluating the safety and effectiveness of ceftaroline versus ceftriaxone with vancomycin in pediatric patients aged 2 months to 17 years with complicated community-acquired pneumonia, and ceftaroline again was found to be well tolerated, with similar rates of adverse events between groups, and as effective as treatment with ceftriaxone and vancomycin.⁴¹

Adverse effects. Ceftaroline has been well tolerated with no safety concerns reported in multiple studies in adults and children.^{41,65,89,198,336} In adults, the most common adverse effects were diarrhea, nausea, headache, and insomnia. Ceftaroline may cause changes in urine color or smell. Ceftaroline did not cause QTc interval prolongation.^{89,336} Although no case of hemolytic anemia was reported during pediatric investigations, the rate of direct Coombs test seroconversion among patients receiving ceftaroline in late-phase pediatric studies has ranged from 17% to 26%.^{41,65,198} This seroconversion may come secondary to changes and/or nonspecific binding of IgG to the red blood cell membrane.^{41,198} Case reports in children and adults have described patients who have experienced agranulocytosis while concurrently receiving ceftaroline. Until more is known about the association between ceftaroline and hematologic disturbances, providers should routinely (e.g., weekly) monitor peripheral white and red blood cell counts and differentials while treating patients with this agent.^{322,360}

Adverse effects associated with cephalosporins in general. The cephalosporins, like the penicillins, are safe for children and have almost no dose-related toxicity. The most common reactions are local, including pain at the injection site or thrombophlebitis with parenteral administration and mild gastrointestinal complaints with oral dosing. Hypersensitivity reactions occur in approximately 1% to 3% of treatment courses and include morbilliform rash, urticaria, and pruritus. Drug fever has been associated with the administration of cephalosporins. Nonspecific antibiotic-associated diarrhea and, less commonly, *C. difficile* toxin-mediated colitis can occur after use of a cephalosporin.

Other adverse effects are rare, and some are unique to one or a few cephalosporins. Physicians should be alert for uncommon reactions, including reversible neutropenia, which can occur after prolonged use of high-dosage cephalosporins; Coombs-positive hemolytic anemia; and bleeding. Altered hemostasis because of hypoprothrombinemia can result when using any cephalosporin that contains a methylthio-tetrazole side chain (cefotetan). These agents act as competitive inhibitors of vitamin K-dependent carboxylase, which converts clotting factors II, VII, IX, and X to their active forms. Gallbladder sludging, biliary pseudolithiasis, and symptomatic obstructive biliary disease rarely have been associated with the administration of ceftriaxone.³⁸³

The cephalosporins may produce allergic reactions similar to those caused by the penicillins. Cross sensitization exists among the cephalosporins, and allergy to one cephalosporin implies allergy to all. Various degrees of immunologic cross reaction of penicillins and cephalosporins have been demonstrated in vitro and in animal models.²⁷⁶ Previously quoted studies suggest that the frequency of allergic reactions to cephalosporins ranges from 5.4% to 16.5% in adult patients with a history of penicillin allergy and 1.0% to 2.5% in those without such a history. The incidence of hypersensitivity to unrelated drugs is increased in some patients who are allergic to penicillin, a finding suggesting that excipients in antibiotic preparations may be responsible for these reactions.³¹⁴ Most patients who are thought to be allergic to penicillin receive cephalosporins without adverse reaction. Data indicate that the risk for an allergic reaction to a cephalosporin challenge among penicillin-allergic subjects with positive skin test responses is 4%. Therefore, the following options are available for individuals with positive skin test responses for penicillin hypersensitivity: administration of an alternative non- β -lactam antibiotic, administration of a cephalosporin by graded

challenge, or desensitization to the cephalosporin. Individuals with a history of penicillin allergy who have negative penicillin skin test responses may receive cephalosporins because they are at no higher risk than the general population for experiencing allergic reactions.²¹³ In the absence of penicillin skin testing, a cephalosporin may be used with caution as an alternative to penicillin in children who have an ambiguous history of rash; however, cephalosporins should be avoided in patients with a known immediate or accelerated reaction to a penicillin. Currently, skin testing to evaluate for cephalosporin hypersensitivity is not possible because the potential cephalosporin haptens are unknown, and no standardized antigen exists.

Some products may cause unexpected reactions, such as bile sludge attributed to ceftriaxone and serum sickness-like disease described with cefaclor. A generalized pruritic rash, similar to erythema multiforme, developed in some children treated with cefaclor, along with fever, purpura, and arthritis with pain and swelling in the knees and ankles. The signs appeared 5 to 19 days after the start of therapy and generally disappeared within 4 to 5 days after discontinuing use of the drug. The children had no previous history of allergy to a penicillin or cephalosporin.²⁵⁴ Levine²¹⁰ compared adverse reactions in children who received cefaclor (1017 patients and 2513 courses) or amoxicillin (1009 patients and 2358 courses). Serum sickness (defined as arthritis or arthralgia in addition to a rash or urticaria) or erythema multiforme occurred in 11 children (1.1%) who received cefaclor but in none of those who received amoxicillin. Studies suggest that serum sickness-like reactions to cefaclor are associated with lymphocyte sensitization.¹⁸⁶

Monobactams

Aztreonam is the prototype monobactam, a name that refers to the unique monocyclic nucleus. This drug has aerobic, gram-negative antibacterial activity similar to that of ceftazidime, but it has no significant gram-positive activity. Unlike most β -lactam antibiotics, aztreonam has the advantage of not inducing β -lactamase activity, and its molecular structure confers a high degree of stability to hydrolysis by β -lactamases. The mechanisms of antibiotic resistance of some gram-negative bacteria include expression of efflux pumps, reduced expression of outer-membrane porin proteins, and production of AmpC-type β -lactamases or ESBLs. In a study conducted from 1998 to 2003, approximately 15% of Enterobacteriaceae in North America were resistant to aztreonam.³⁰⁷ However, of 442 ESBL-producing Enterobacteriaceae collected between June 2013 and September 2014 from adult patients in US hospitals, only 7% were susceptible to aztreonam.³³⁴ Although it is a β -lactam, aztreonam is weakly immunogenic and can be used in patients with minor forms of β -lactam allergy. Its use in pediatrics is indicated as a secondary agent for the intravenous treatment of lower respiratory tract, skin and soft tissue, urinary tract, and intra-abdominal infections caused by susceptible pathogens. Higher doses of aztreonam may be warranted for pediatric patients with cystic fibrosis. Aztreonam and aminoglycosides are synergistic in vitro against most strains of *P. aeruginosa*, many strains of Enterobacteriaceae, and other aerobic gram-negative bacilli. The safety and efficacy of aztreonam have not been established for infants younger than 9 months of age or for children with impaired renal function. However, aztreonam has been used with favorable outcomes in premature and term neonates, as well as in young infants. Updated breakpoints for enteric gram-negative organisms to aztreonam were released in 2010. The revised breakpoints include 4 μ g/mL or less, 8 μ g/mL, and 16 μ g/mL or greater for susceptible, intermediate, and resistant organisms, respectively.³⁶⁷ Aztreonam lysinate for inhalation is a novel monobactam formulation approved by the FDA in February 2010 for patients with cystic fibrosis who are colonized with *P. aeruginosa*. For children 7 years of age or older and adults, the dose recommended for inhaled aztreonam is 75 mg three times daily for 28 days.^{281,374}

Carbapenems

Carbapenems differ from penicillin by virtue of the substitution of a sulfur atom by a carbon atom at position 1 of the β -lactam ring and possession of an unsaturated bond between carbon atoms at positions 2 and 3 in the structure. The carbapenem class of antimicrobial agents exhibits the broadest spectrum of activity of all β -lactam antibiotics;

these agents are active against most clinically significant gram-positive and gram-negative pathogens, including anaerobic organisms. Because they are acid-labile in the stomach, they must be administered parenterally.⁹⁰ Three carbapenems, imipenem-cilastatin, meropenem, and ertapenem, are approved for use in children.

Imipenem-Cilastatin

Imipenem-cilastatin was the first carbapenem evaluated for the treatment of severe bacterial infections in children. Extensive hydrolysis of imipenem by dehydropeptidase I occurs in the proximal renal tubule and results in the production of a potentially nephrotoxic inactive metabolite. Consequently, imipenem must be administered with cilastatin, an inhibitor of dehydropeptidase I. Despite favorable in vitro efficacy against a broad spectrum of bacterial pathogens, the clinical suitability of this antibiotic is limited because of the drug's epileptogenic potential, especially in children with bacterial meningitis. Imipenem causes seizures presumably by acting as a competitive inhibitor of γ -aminobutyric acid, an inhibitory neurotransmitter.⁹⁰ Of concern is that imipenem acts as a strong inducer of production of ESBL and may select for β -lactam resistance.⁹⁴ Imipenem-cilastatin is indicated for children with severe non-CNS infections caused by susceptible organisms. The dose must be reduced for children with impaired renal function. With the advent of meropenem, imipenem-cilastatin has been used less frequently in pediatrics.

Meropenem

Meropenem was approved for use in children in 1996. It is structurally related to imipenem. However, it is more stable against degradation by renal dehydropeptidase I and therefore does not require coadministration with cilastatin. On the basis of its superior safety and efficacy, meropenem generally is considered the preferred carbapenem for treatment of childhood infections.

Mechanisms of action. As with other β -lactam antibiotics, meropenem is bactericidal against susceptible bacteria because it inhibits bacterial cell wall synthesis. The *trans* configuration of the hydroxyethyl side chain and hydrogen atoms protect the parent β -lactam structure from inactivation by the most common β -lactamases: almost all Bush groups 1 and 2 (Ambler classes A, C, and D) β -lactamase-producing organisms, including those that produce ESBLs (*Citrobacter*, *Enterobacter*, *E. coli*, *Klebsiella* spp., and *P. mirabilis*) or AmpC β -lactamases (*Citrobacter*, *Enterobacter*, *Pseudomonas*, and *Serratia*). In addition, the pyrrolidine side chain enhances the compound's antipseudomonal activity.⁹⁴

Mechanisms of resistance. Resistance may be intrinsic or acquired and is mediated by numerous mechanisms: (1) some strains of *P. aeruginosa* are deficient in the cell wall porin proteins (OprD) that usually facilitate intracellular penetration; (2) efflux pumps in some gram-negative bacteria are capable of excreting carbapenems; (3) *S. maltophilia* and some other gram-negative pathogens possess uncommon metallo- β -lactamases, the so-called carbapenemases (i.e., Bush groups 3a and 3b and Ambler class B), which form a diverse group of β -lactamases comprising the IMP and VIM families, and SPM1 and GIM1 enzymes; these carbapenemases have the ESBL and AmpC antibiotic substrate profile; (4) some gram-negative bacteria possess clavulanic acid-inhibited carbapenemases consisting of the *K. pneumoniae* carbapenemases (KPCs) (i.e., Bush group 2f and Ambler class A) or OXA enzymes (i.e., Bush group 2d and Ambler class D); and (5) MRSA strains and *E. faecium* have altered PBPs, which account for their inherent resistance. Furthermore, meropenem acts as a weak inducer of ESBLs.^{54,94} At present, the risk that a single-step spontaneous mutation causes resistance among *Pseudomonas* spp. appears to be low.

In vitro activity. Meropenem has equivalent or slightly less in vitro potency than imipenem against gram-positive pathogens, but it is significantly more active against gram-negative organisms. The spectrum of activity of meropenem encompasses streptococci (excluding many strains of penicillin- and cefotaxime-nonsusceptible *S. pneumoniae*), oxacillin-susceptible staphylococci, ampicillin-susceptible enterococci, *L. monocytogenes*, *H. influenzae*, *N. meningitidis*, Enterobacteriaceae, most strains of *P. aeruginosa*, and anaerobes (including β -lactamase-positive strains of *B. fragilis*). Pathogens resistant to meropenem are *Stenotrophomonas*, MRSA, *E. faecium*, approximately 10% of *Pseudomonas*

strains, and most strains of penicillin and cefotaxime-nonsusceptible *S. pneumoniae*.^{54,55,61,358} In vitro tests indicate that meropenem acts synergistically with aminoglycoside antibiotics against some isolates of *P. aeruginosa*.¹⁶²

Pharmacokinetics. Meropenem exhibits nearly linear pharmacokinetics; increases in dosage result in approximately proportional increases in the peak plasma concentration and AUC.⁴⁰ Only 2% of the drug is bound to plasma proteins, and the drug is distributed widely into tissues and fluids.⁹⁰ The elimination half-life declines with increasing age (premature neonates, 2.9 hours; term neonates, 2 hours; children, 1.1 hours; adults, 1 hour) and is longer than that for imipenem. Because meropenem is cleared primarily by glomerular filtration, the dosage should be reduced in children with renal dysfunction.⁵⁴ Furthermore, meropenem is cleared efficiently by hemodialysis; therefore, it should be administered after the patient undergoes this procedure. Pharmacodynamic studies indicate that a favorable bacteriologic outcome is best predicted by the duration of the dosing interval for which the meropenem plasma concentration exceeds the MIC₉₀ of the target pathogen.⁹⁰ Accordingly, a dose of 20 mg/kg every 8 hours achieves optimal plasma concentrations (50 to 60 μ g/mL) for systemic infections that do not involve the CNS,⁴² whereas a dose of 40 mg/kg every 8 hours is recommended for patients with cystic fibrosis because of accelerated drug excretion.¹⁵⁴ Penetration of meropenem through inflamed meninges is approximately 8% of the mean plasma concentration. Consequently, a dose of 40 mg/kg every 8 hours is required to achieve mean peak CSF concentrations of 0.9 to 6.5 μ g/mL and ensure effective treatment of bacterial meningitis.^{90,268} An administration schedule of every 12 hours probably is appropriate for neonates because of their immature renal function.⁴⁰

Indications for use. The FDA has approved meropenem as monotherapy for susceptible organisms causing intra-abdominal infections and bacterial meningitis in children older than 2 months of age. Meropenem should be reserved for treatment of cephalosporin-resistant nosocomial pathogens, severe polymicrobial infections with favorable susceptibility profiles, and infections that fail to respond to other antimicrobial agents. Meropenem monotherapy has clinical and microbiologic efficacy equivalent to that of third-generation cephalosporin-based regimens for septicemia and infections of the CNS, abdominal cavity, lower respiratory tract, urinary tract, and skin.^{52,268} In addition, meropenem monotherapy has been shown to be equivalent to ceftazidime and amikacin and to piperacillin-tazobactam for empirical treatment of febrile children with neutropenia.^{86,275} Clinical efficacy against cephalosporin-resistant pathogens also has been demonstrated in patients with cystic fibrosis.¹⁵⁴ In view of increasing resistance of pneumococci to β -lactam antibiotics, it is prudent to administer vancomycin with meropenem for empirical treatment of suspected bacterial meningitis until CSF microbiologic results are available. Given the significant emergence of multidrug-resistant gram-negative pathogens, empiric combination therapy with an aminoglycoside should be considered for suspected *P. aeruginosa* infections or infections caused by Enterobacteriaceae in critically ill or immunocompromised patients in view of emerging resistant strains and potential antibiotic synergy until microbiologic data become available. The effectiveness of meropenem for neonatal infections has been assessed in small, noncomparative studies that demonstrated a favorable clinical response in neonates.^{83,162} Results from an open-label randomized controlled trial comparing the efficacy of meropenem with ampicillin plus gentamicin or cefotaxime plus gentamicin for the treatment of late-onset sepsis in neonates and young infants are awaited.²²⁷

Adverse effects. Data from well-designed clinical trials indicate that meropenem has clinical and laboratory adverse event profiles that are equivalent to those of comparable antibiotic regimens. In contrast to treatment with imipenem-cilastatin, no increased risk for seizures exists in children with or without meningitis who are treated with meropenem,¹⁹⁵ presumably because meropenem has less affinity than imipenem for the γ -aminobutyric acid receptor. Meropenem can be given intravenously as small-volume bolus injections (over a course of 3 to 5 minutes) without inducing nausea or vomiting. The most common adverse reactions include diarrhea (4%), rash (2%), and vomiting (1%).⁵⁴

Ertapenem

Ertapenem is a newer, long-acting, parenteral carbapenem that initially was approved for use in adults in 2001. An indication for children was approved in 2005. However, clinical experience with this agent in children is limited. Ertapenem is distinctive because it is administered in a single daily dose in adolescents and adults and is stable against hydrolysis by many β -lactamases, except metallo- β -lactamases produced by certain bacterial nonfermenters, particularly *Pseudomonas* and *Acinetobacter*.²³³ Apart from these organisms, its antimicrobial spectrum is similar to that of meropenem. Ertapenem has restricted activity against methicillin-resistant staphylococci, penicillin-nonsusceptible pneumococci, enterococci, *Pseudomonas* spp., and *Acinetobacter* spp.¹⁸⁷ The agent may be administered by intravenous or intramuscular routes. It exhibits nonlinear pharmacokinetics because of its concentration-dependent protein binding. The drug is excreted renally, and dosages need to be adjusted in patients with renal insufficiency.

Ertapenem is indicated for the treatment of patients 3 months of age and older with complicated intra-abdominal infections, complicated skin and soft tissue infections, community-acquired pneumonia, complicated urinary tract infections, and acute pelvic infections. Ertapenem is not recommended for the treatment of meningitis because drug concentrations in the CSF are subtherapeutic. The recommended dose in patients 3 months to 12 years of age is 15 mg/kg given parenterally twice daily, up to a maximum of 1 g/day. In older children and adults, the recommended dose is 1 g given once daily. The recommended duration is up to 14 days for intravenous administration. The most common adverse reactions, which include diarrhea, vomiting, and pain at the site of infusion, have rates comparable to those of other parenteral broad-spectrum β -lactam antimicrobials. Seizures have been reported in patients receiving ertapenem and may occur more commonly in individuals with underlying seizure disorders, brain lesions, or renal dysfunction.

Doripenem

Doripenem is a parenteral carbapenem approved in 2007 for use in adults with complicated intra-abdominal infections and complicated urinary tract infections and is currently under review for treatment of hospital-acquired pneumonia, including ventilator-associated pneumonia, and catheter-related bacteremia. Doripenem has activity against gram-positive organisms, including MSSA, penicillin-susceptible and non-susceptible *S. pneumoniae*, and *E. faecalis*. Activity against gram-negative bacteria is similar to that of meropenem and includes ESBL-producing strains. It also has good anaerobic coverage, including *B. fragilis*.^{75,274}

Mechanisms of Resistance to β -Lactam Antibiotics

Bacteria can acquire resistance to an antibiotic by at least four mechanisms: (1) alteration in the antimicrobial target, (2) decreased uptake of the antibiotic by expression of efflux pumps or by reduction of cell membrane permeability that is determined by porin channels, (3) production of an enzyme that inactivates the antibiotic, and (4) production of an alternative metabolic pathway that bypasses the action of the drug.³⁴² With respect to β -lactam antibiotics, resistance involves alterations in PBPs, leading to decreased affinity for the β -lactam (this mechanism of resistance is observed in methicillin-resistant strains of *S. aureus* and penicillin-resistant strains of *S. pneumoniae*); decreased permeability of the bacterial cell wall, resulting in diminished amounts of β -lactam reaching the PBPs; or production of β -lactamases that hydrolyze the β -lactam ring. Hydrolysis of β -lactams is the mechanism that is most significant clinically. Gram-positive bacteria excrete their β -lactamases outside the cell wall, whereas the β -lactamases of gram-negative bacteria remain in the periplasmic space. The spectrum of β -lactamase activity involves (1) narrow-spectrum penicillinases that preferentially hydrolyze penicillins; (2) broad-spectrum β -lactamases that hydrolyze penicillins and cephalosporins equally well; (3) cephalosporinases that preferentially hydrolyze cephalosporins and are resistant to inhibition by clavulanic acid; (4) ESBLs that hydrolyze first-, second-, and third-generation cephalosporins but are susceptible to inhibition by clavulanic acid; and (5) carbapenemases that inactivate all β -lactams, including imipenem-cilastatin.⁶³

Broad-spectrum β -lactamases were initially recognized in clinical isolates in the 1980s. Currently, the spread of ESBLs among enteric gram-negative organisms in both hospital and community settings has become an important public health problem. Rates of ESBL production have been high in Latin America, Asia and the Pacific region, Europe, and North America. For Latin America, the rates of ESBL production for *E. coli* and *K. pneumoniae* were 24.5 and greater than 40%, respectively, from 2004 to 2012.¹⁸⁸ β -Lactamases are classified on the basis of their (1) responses to β -lactamase inhibitors, (2) spectrum of antibiotic substrates (Bush-Jacoby-Medeiros classification, groups 1 to 4), or (3) primary molecular structure (i.e., Ambler classification: serine β -lactamases, which are class A, C, or D; and metallo- β -lactamases, which are class B). Bush group 2 corresponds to Ambler classes A and D, which are encoded frequently by genes carried on plasmids and easily spread among different species, whereas Bush groups 1 and 3 (Ambler classes C and B, respectively) are frequently encoded by chromosomal genes and therefore confined to certain species.^{94,273} Chromosomally mediated, inducible Bush group 1 β -lactamases that are produced by certain species of *Citrobacter*, *Enterobacter*, *Morganella*, *Pseudomonas*, and *Serratia* are not inhibited by the β -lactamase inhibitors, and, consequently, they remain resistant to the accompanying β -lactam. However, *Bacteroides*, *Klebsiella*, *Legionella*, and *Moraxella* spp. produce chromosomally mediated β -lactamases that are effectively inactivated. Clavulanic acid and tazobactam are more potent inhibitors of β -lactamases. Furthermore, clavulanate induces Bush group 1 enzymes. Disks containing β -lactamase inhibitors can be used in the clinical microbiology laboratory to detect pathogens that produce Ambler class A ESBLs of the TEM and SHV types that may be overlooked otherwise.⁶⁴

The ESBLs are classified in the Ambler class A and the functional (Bush group) 2be. ESBLs are present in various members of the Enterobacteriaceae family, particularly *E. coli* and *K. pneumoniae*, but they are also found in nonfermentative gram-negative bacteria, including *P. aeruginosa* and *A. baumannii*. Traditionally, β -lactamases derived mainly from the type A (Ambler) or 2be (Bush) groups, most commonly TEM (1 and 2) and SHV (1), derived by point mutations of the parent enzymes. These β -lactamases degrade penicillin, ampicillin, antipseudomonal penicillins, and narrow-spectrum cephalosporins (i.e., cefazolin and cefuroxime). They are inhibited by clavulanic acid, and this allows for laboratory detection of these enzymes. Another type of class A ESBL is the expanded-spectrum CTXM, which is becoming more prevalent, particularly in *E. coli* and *K. pneumoniae*. It preferably hydrolyzes cefotaxime in contrast to ceftazidime and degrades aztreonam and the same products hydrolyzed by TEM and SHV; for some enzymes cefepime may be a substrate. More than 100 enzymes on the CTXM group have been identified, and they can be divided into five groups on the basis of amino acid changes (i.e., CTXM1, CTXM2, CTXM8, CTXM9, and CTXM25). This enzyme has been disseminated on plasmids and is also inhibited by clavulanic acid. Carbapenemases of the type KPC (*Klebsiella pneumoniae* carbapenemases 1, 2, and 3) are also included on the Ambler class A β -lactamases, and they have the same substrates hydrolyzed by CTXM as well as cephamycins and carbapenems. They are inhibited by amoxicillin-clavulanate. Ambler class B (Bush group 3) requires divalent cations, particularly Zn^{2+} , at the active site. These enzymes can be chromosomally encoded or transferred by plasmids. This group includes the IMP and VIM families, as well as GIM1 and SPM1 β -lactamase. These β -lactamases are included in the group of carbapenemases and degrade the same products hydrolyzed KPC. They are not inhibited by clavulanic acid. Ambler class C (Bush group 1) β -lactamases are encoded by chromosomes. They are referred as AmpC and degrade substrates of the TEM and SHV, oxyiminocephalosporins (i.e., cefotaxime, cefpodoxime, ceftazidime, and ceftriaxone), monobactams, and cephamycins (i.e., cefotetan and cefoxitin). These enzymes are not inhibited by clavulanic acid. The OXA family β -lactamase (Ambler class D) has higher rates of hydrolysis for oxacillin in contrast to penicillin and also degrades substrates of CTXM. These enzymes are resistant to β -lactamase inhibitors. Plasmid-encoded OXA enzymes have been found in *P. aeruginosa*.^{108,168,292}

Laboratory detection of ESBL includes phenotypic and genotypic tests. Phenotypic tests include screening tests by testing for resistance to cefpodoxime (hydrolyzed by all TEM, SHV, and CTXM ESBLs), cefotaxime, ceftazidime, ceftriaxone, and aztreonam. Then a confirmatory step is performed by demonstrating synergy between these agents and clavulanic acid (double-disk synergy test, combination disk method, or ESBL E tests). Genotypic tests consist of polymerase chain reaction amplification of specific genes.¹⁰⁸

Treatment of ESBL-producing organisms represents a challenge. In vitro sensitivity may not correlate with effective treatment in vivo. Organisms producing TEM and SHV-type ESBL may appear susceptible to cefepime and piperacillin-tazobactam in vitro but may be nonsusceptible when the inoculum is increased to 10^5 to 10^7 organisms. In these circumstances it may be difficult to ensure good concentrations of the antibiotic at the site of the infection (above the MIC). A carbapenem remains the antibiotic of choice for treatment of ESBL-producing organisms. AmpC-producing strains are typically susceptible to carbapenems; however, diminished porin expression can make it a carbapenem-resistant strain. Bacteria expressing IMP, VIM, or OXA-type carbapenemases usually remain susceptible to aztreonam. Care should be taken in selecting the correct antibiotic because resistance to fluoroquinolones and aminoglycosides can occur.¹⁶⁸

Glycopeptides

Vancomycin

Vancomycin, first isolated from *Amycolatopsis orientalis* (formerly called *Streptomyces*, then *Nocardia*) in soil samples from Borneo, is a high-molecular-weight, complex, soluble glycopeptide.²⁷⁸ Because of a lack of adequate therapy for penicillinase-producing staphylococci, vancomycin was approved expeditiously by the FDA in 1956 before exhaustive pharmacologic and toxicologic studies had been performed. Original preparations contained fermentation by-products that caused significant toxicity. Once the penicillinase-resistant penicillins were developed, vancomycin use decreased until the emergence of methicillin-resistant staphylococci in the late 1970s.

Mechanisms of action. Vancomycin is slowly bactericidal against most susceptible gram-positive bacteria, except enterococci, for which it is bacteriostatic. It forms complexes with the D-alanyl-D-alanine portion of peptide precursor units and thus prevents polymerization of the phosphodisaccharide pentapeptide lipid complex and cross-linking of peptidoglycan during the second stage of cell wall synthesis. Because the site of action of vancomycin is distinct from that of β -lactam antibiotics, no cross resistance among the drugs and no competitive inhibition exist. Like penicillin, vancomycin exerts its antimicrobial effect on bacteria in the active growth phase. Additionally, vancomycin alters cytoplasmic membrane permeability and impairs RNA synthesis. Animal infection models suggest that the drug exhibits time-dependent bactericidal activity against susceptible organisms, as well as a moderately long in vitro postantibiotic effect. The most important pharmacokinetic and pharmacodynamic parameter that correlates with antimicrobial efficacy is the ratio of the 24-hour AUC to the MIC (24-hour AUC/MIC).⁹¹ A lag phase before the onset of rapid killing has been demonstrated in serum killing studies.³

Mechanisms of resistance. Resistance can be categorized into three types: tolerance, acquired resistance, and inherent resistance. Some susceptible gram-positive bacteria, especially enterococci, are tolerant to the bactericidal activity of vancomycin; that is, vancomycin inhibits but does not kill the bacteria (MBC/MIC ratio >32). Staphylococci tolerant to vancomycin can have autolysin deficiencies. Although most resistance to vancomycin by gram-positive bacteria is acquired, three genera of gram-positive organisms are inherently resistant to vancomycin: *Erysipelothrix*, *Leuconostoc*, and *Pediococcus*. Nine gene clusters currently are known to be associated with vancomycin resistance in enterococci.¹⁴⁵ The *vanA*, *vanB*, *vanD*, and *vanM* gene clusters that cause vancomycin resistance by altering the terminal amino acids of peptidoglycan precursors from D-Ala-D-Ala to D-Ala-D-lactate (i.e., high-level resistance), while the *vanC*, *vanE*, *vanG*, *vanL*, and *vanN* gene clusters cause resistance through the formation of D-Ala-D-serine (i.e., low-level resistance).¹⁴⁵ The most clinically relevant vancomycin

resistance determinants are *vanA* and *vanB*. The *VanA* gene encodes the VanA phenotype (vancomycin MIC >256 and teicoplanin resistance), which is on a plasmid that is easily transferable by conjugation to other enterococci. The VanB phenotype also is transferable and encodes vancomycin but not teicoplanin resistance. The presence of an inducer such as vancomycin or teicoplanin, another glycopeptide that has not been approved for use in the United States, activates the transcription of genes that encode ligases necessary for resistance to vancomycin. Some enzymes make cell wall precursors ending in D-alanyl-D-lactate located at the end of the pentapeptide side chain, to which vancomycin binds with very low affinity. Other enzymes inhibit or alter the synthesis of endogenous cell wall precursors ending in D-alanyl-D-alanine, to which vancomycin is unable to bind. The finding that vancomycin resistance genes can be transferred experimentally from vancomycin-resistant enterococci (VRE) to staphylococci highlights the potential risk for spread of resistance by means of naturally occurring plasmid or transposon-mediated conjugative systems.²⁵² Although vancomycin resistance can affect susceptibility to other investigational glycopeptides, no cross resistance exists between vancomycin and other unrelated antibiotics. Resistance to vancomycin rarely develops during appropriate therapy, perhaps because of its multiple mechanisms of action, but prolonged or indiscriminate use of the drug can contribute to selective pressure and result in the development of vancomycin-resistant enterococci colonizing the gut. Of great concern is the emergence of invasive strains of multidrug-resistant enterococci ($\leq 14\%$ of health care-associated enterococcal strains)²²⁶ and staphylococci, for which only a few therapeutic options exist, including linezolid and other antimicrobials not approved for use in children such as quinupristin-dalfopristin, daptomycin, and tigecycline (a novel glycylcycline antibiotic). The first strains of *S. aureus* with intermediate resistance to vancomycin/glycopeptide (VISA/GISA) were detected in the United States in 1997. Soon thereafter, three cases of vancomycin-resistant *S. aureus* were isolated. The mechanism for this high-level vancomycin resistance involves the horizontal transfer of a transposon containing *VanA* and associated genes from vancomycin-resistant enterococci.²⁹⁴ Glycopeptide-resistant isolates were found to have thicker extracellular matrices, a characteristic that may cause vancomycin to become trapped in the outer layers of the cell wall and may limit access to the cytoplasmic membrane where the functional targets are located. Pneumococci tolerant to vancomycin were described first in 1999.²⁶⁷ These strains escape lysis and killing by vancomycin because of an alteration in the regulation of autolysin. Their prevalence is 4% to 10% of nasopharyngeal and invasive isolates, and they are associated with increased mortality when etiologic in meningitis.³⁰¹ In 2006, the CLSI modified the MIC breakpoints for *S. aureus* to vancomycin: from 4 $\mu\text{g/mL}$ or less to 2 $\mu\text{g/mL}$ or less for "susceptible," from 8 to 16 $\mu\text{g/mL}$ to 4 to 8 $\mu\text{g/mL}$ for "intermediate," and from 32 $\mu\text{g/mL}$ or greater to 16 $\mu\text{g/mL}$ or greater for "resistant." This change was made to increase the detection of heterogeneously resistant isolates and based on clinical data showing less response to vancomycin when the MIC is 4 $\mu\text{g/mL}$ or greater.³⁴³ The CDC recommends that the use of vancomycin be restricted appropriately to reduce the risk for inducing vancomycin resistance.⁷¹

In Vitro activity. The in vitro spectrum of activity for vancomycin is limited to gram-positive aerobic and anaerobic bacteria, with little, if any, activity against aerobic or anaerobic gram-negative bacilli, except *Chryseobacterium meningosepticum*. Group A streptococci, pneumococci, *Corynebacterium* spp., and *C. difficile* are highly susceptible to vancomycin, whereas *L. monocytogenes*, microaerophilic and anaerobic streptococci, enterococci, coagulase-positive and coagulase-negative staphylococci, *Bacillus anthracis* and other spp., *Lactobacillus*, *Actinomyces*, and other *Clostridium* spp. have higher MIC values that are still in the susceptible range. Pathogens resistant to vancomycin include *Erysipelothrix* and *Leuconostoc* and *Pediococcus* spp., which can cause serious infections in immunocompromised patients. The bactericidal activity of vancomycin combined with gentamicin has been shown to be synergistic in vitro against strains of enterococci (provided there is no high-level gentamicin resistance; MIC $>2000 \mu\text{g/mL}$), nonenterococcal group D streptococci, viridans streptococci, and most

methicillin-susceptible *S. aureus* and MRSA. Addition of rifampin, gentamicin, or both results in improved cure rates for *S. epidermidis* prosthetic valve endocarditis.²²⁶ Although vancomycin has activity against many gram-positive bacteria, it is not the most active agent for these organisms, but it is the drug of choice for multidrug-resistant bacteria such as methicillin-resistant staphylococci and highly penicillin-resistant and cephalosporin-resistant pneumococci.

Pharmacokinetics. Intravenous administration of vancomycin is preferred because intramuscular injection causes pain and tissue necrosis. Intravenous preparations must be diluted further in normal saline or dextrose solutions before beginning slow infusion. Vancomycin is approximately 55% bound to serum proteins and diffuses well into most body tissues, with adequate concentrations achieved in pericardial, pleural, ascitic, bone, and synovial fluids, but not in aqueous humor or bile. Vancomycin does not diffuse well into CSF in the absence of inflamed meninges, but CSF concentrations of 7% to 21% of concomitant serum levels can be achieved during therapy for meningitis when higher doses (15 mg/kg every 6 hours) are administered. The bone-to-serum ratio of vancomycin is 10%, but this figure increases up to 30% in infected bone. Vancomycin remains active at pH 6.5 to 8, and concentrations achieved in abscess fluid approximate serum levels.²²⁶ Intrathecal or intraventricular administration has been used infrequently for CNS infections that are difficult to eradicate.²²⁵ Vancomycin is not metabolized significantly and is excreted by glomerular filtration. The mean serum elimination half-life in adults with normal renal function is 6 hours. For children, it ranges from 5 to 10 hours in newborns and 4 hours in older infants to 2 to 3 hours in children. In anephric patients, the elimination half-life extends to 7 or more days. Hemodialysis removes small amounts of vancomycin, whereas peritoneal dialysis may reduce serum concentrations by approximately 40%. Nomograms and patient-individualized bayesian dosing regimens have been used for vancomycin dosing in renal failure in adults.^{204,243}

Current recommendations for vancomycin monitoring in adult patients include checking trough concentrations rather than peak values as the most accurate method for vigilance over efficacy and toxicity. Trough values should be checked before the fourth dose of the antibiotic (steady state). Minimal concentration should be maintained above 10 µg/mL, and target concentrations of 15 to 20 µg/mL are preferred for complicated infections secondary to *S. aureus* in adults (bacteremia, endocarditis, osteomyelitis, meningitis, and hospital-acquired pneumonia).^{216,303}

Indications for use. Because of the potential for development of resistance, vancomycin should be reserved for patients with moderate-to-severe infections caused by vancomycin-susceptible bacteria that are resistant to other antibiotics. Vancomycin can be used for the treatment of infections caused by β-lactam-susceptible and vancomycin-susceptible bacteria in patients with hypersensitivity reactions to β-lactam antimicrobial agents. Empirical therapy for patients with ventricular shunt-related and catheter-associated infections frequently includes vancomycin to provide activity against coagulase-negative staphylococci and MRSA. Vancomycin can be used in combination with gentamicin, rifampin, or both for bactericidal synergistic activity to treat documented prosthetic device-related *S. epidermidis* infections, methicillin-resistant staphylococcal endocarditis, or endocarditis caused by high-level penicillin-resistant, aminoglycoside-susceptible strains of enterococci. *S. epidermidis* infections of long-term intravenous catheters usually can be cured without removal of the device.²²⁶ In addition, vancomycin is the drug of choice in patients with immediate-type hypersensitivity to penicillins and other β-lactam antibiotics for prophylaxis (e.g., in gastrointestinal or genitourinary procedures) or treatment of endocarditis caused by streptococci, enterococci, and staphylococci.^{22,369} Empirical treatment of bacterial meningitis suspected or proved to be caused by *S. pneumoniae* in children 1 month of age or older should consist of vancomycin in addition to a third-generation cephalosporin until susceptibility data are available; if cephalosporin resistance is documented, rifampin should be added to the regimen. Vancomycin also is indicated for the treatment of infections with penicillin-resistant streptococci, *C. jeikeium*, and *Bacillus* spp. and penicillin-resistant enterococci, as well as for bacteremia, pneumonia, cellulitis, and osteomyelitis caused by methicillin-resistant staphylococci. Some experts

advocate the addition of nafcillin, oxacillin, gentamicin, or rifampin for optimal coverage of oxacillin-susceptible *S. aureus* in severely ill patients who are receiving empirical treatment with vancomycin because certain strains of staphylococci are tolerant to vancomycin.¹³⁶ Proof of enhanced efficacy in children with combination therapy in this setting is lacking. Although nonabsorbable oral vancomycin is effective therapy for *C. difficile* colitis, oral metronidazole represents first-line therapy; vancomycin should be given only for metronidazole treatment failures, to limit the development of vancomycin-resistant enterococci. Vancomycin is among the agents of choice for the treatment of meningitis caused by *C. meningosepticum*.

Adverse effects. The purification of vancomycin allegedly decreased the frequency of adverse reactions noted several decades ago. The most common adverse effect is “red man” or “red neck” syndrome or glycopeptide-induced anaphylactoid reaction manifested as flushing of the face and upper part of the trunk, pruritus during vancomycin infusion, angioedema, and, rarely, hypotension. Vancomycin directly causes release of histamine from mast cells by non-immune-mediated mechanisms. Because it is a dose- and rate-dependent reaction, administering doses less than 500 mg, prolonging the infusion period to at least 1 hour, or both decreases the risk for occurrence. Pretreatment with histamine-1-receptor antagonists (i.e., diphenhydramine or hydroxyzine) prevents the development of this reaction, and symptoms usually resolve promptly after discontinuation of the infusion.

Controversy surrounds the issue of vancomycin-induced ototoxicity and nephrotoxicity.⁶⁰ Such toxicity has not been demonstrated in experimental animal models. Although numerous cases of toxicity in humans have been reported, the literature is difficult to interpret because of confounding variables, including recent or concurrent use of aminoglycosides or other ototoxic or nephrotoxic agents, lack of identification of antecedent otologic or renal disease, and inconsistencies in sampling methods when measuring serum vancomycin concentrations. Tinnitus and high-tone hearing loss have been associated with the administration of vancomycin, particularly when the peak serum levels exceed 50 µg/mL. If vancomycin is ototoxic, whether toxic peak or toxic trough serum concentrations are responsible is not clear. Several studies suggest an increased risk for nephrotoxicity when aminoglycosides are used concurrently with vancomycin, especially when they are administered in critically ill patients.^{132,287} Other adverse effects seen occasionally with the use of vancomycin include reversible neutropenia, thrombocytopenia, drug fever, and macular rash.

The usefulness of serum vancomycin concentration determinations is controversial because a definitive relationship between vancomycin concentration and clinical outcome has not been proved, and several recent studies have suggested that higher vancomycin troughs did not improve outcomes but were associated with increased nephrotoxicity.^{26,238} Until the significance of vancomycin serum concentration determinations has been clarified, monitoring has been suggested for the following clinical situations only: (1) patients with altered renal function, including premature infants; (2) patients receiving larger than normal dosages, especially those with meningitis in whom adequate CSF values are necessary; (3) anephric patients undergoing hemodialysis (to avoid subtherapeutic vancomycin concentrations during prolonged dosing intervals); and (4) patients receiving concomitant therapy with nephrotoxic agents.³⁰³ Because serum vancomycin values commonly are subtherapeutic in the first days of treatment for severe sepsis, presumably because of larger volumes of distribution of vancomycin in these ill children, we recommend an initial dosage of 60 mg/kg per day in four divided doses.

Glycopeptides

Telavancin

Other semisynthetic glycopeptides approved for adults include telavancin and dalbavancin. They may have some advantage over vancomycin and daptomycin in that resistance of MRSA is less likely because of their dual mechanisms of action. Telavancin was approved by the FDA in 2009 for treatment of complicated skin and skin structure infections caused by susceptible gram-positive bacteria in adults. It is a lipoglycopeptide that contains a hydrophobic side chain linked to the vancosamine sugar and a hydrophilic group on the 4 position of amino acid

7. The hydrophobic chain provides improved binding activity for D-alanine-D-alanine-containing peptidoglycan intermediates. Its dual mechanism of action includes binding the peptidoglycan precursor at the D-alanine-D-alanine terminus with subsequent inhibition of transglycosylation (peptidoglycan polymerization) and then inhibition of transpeptidation. The second mode of action includes binding to the cell membrane and triggering rapid concentration-dependent dissipation of cell membrane potential with leakage of cytoplasmic adenosine triphosphate (ATP) and potassium loss. Telavancin is active against MSSA, MRSA, GISA, hGISA, coagulase-negative staphylococci, streptococci (including group A and group B β -hemolytic streptococci and *S. pneumoniae*), *Clostridium* spp., and *Actinomyces israelii*. It does not have activity against VRE (both VanA and VanB). It has high level of protein binding (~93%) and small volume of distribution. It is not inactivated by surfactant. Telavancin is mainly eliminated by renal excretion.³¹³

Dalbavancin

Dalbavancin is a lipoglycopeptide antibiotic originating from modifications to a teicoplanin-like antibiotic, which is an analogue to vancomycin. Dalbavancin gained FDA approval in 2014 for use in adult patients with acute bacterial skin and skin structure infections. Similar to vancomycin, dalbavancin demonstrates activity against gram-positive pathogens including MRSA, streptococci, and enterococci. However, this agent has a half-life of greater than 1 week, which is an advantageous pharmacokinetic parameter allowing once-weekly dosing.^{53,181,325}

Mechanisms of action. Similar to other lipoglycopeptide members of the glycopeptide antimicrobial family, the heptapeptide core of dalbavancin facilitates inhibition of key steps in bacterial cell wall synthesis, namely transglycosylation and transpeptidation.^{181,325,376} Modifications to the heptapeptide core result in differences in the spectrum of coverage between lipoglycopeptides and the degree of activity of these agents against select gram-positive organisms. In the case of dalbavancin, increased activity against staphylococci originates from the addition of a basic amide group to the heptapeptide core. Along with modifications of the heptapeptide core, the addition of a lipophilic side chain results in the extended half-life of dalbavancin and also serves to anchor the molecule to the bacterial cell membrane. This anchoring of dalbavancin enhances antimicrobial activity due to increased binding affinity at the site of inhibition, the growing peptidoglycan chain.³⁷⁶

In vitro activity. Dalbavancin demonstrates 8- to 16-fold greater in vitro potency against susceptible streptococci and staphylococci when compared to the activity of vancomycin and daptomycin.^{177,325} Further, the in vitro potency of dalbavancin against *Staphylococcus aureus* is unaffected by the presence of methicillin resistance amongst isolates [independent of the isolates sensitivity to beta-lactam agents]. Even in those *S. aureus* isolates found to be vancomycin-intermediate (VISA), dalbavancin continues to demonstrate MIC values four- to eightfold lower than those reported for vancomycin.¹⁷⁷ Dalbavancin is active against both vancomycin-susceptible *Enterococcus faecalis* and *faecium* with an MIC of 0.125 $\mu\text{g/mL}$. While dalbavancin demonstrates in vitro activity against organisms with the VanB resistance gene, it is inactive against those with the VanA resistance gene. Thus, VRE harboring the VanA resistance gene, the majority of VRE isolates in the United States, have much higher dalbavancin MIC values compared to those isolates demonstrating vancomycin-resistance secondary to the presence of the VanB resistance gene.³²⁵ At present, the clinical utility of dalbavancin for treating infections caused by enterococci remains unknown, as only limited in vitro data exist.¹⁸¹

Pharmacokinetics. Dalbavancin demonstrates nearly linear pharmacokinetics over a broad dosing range; increases in dosage result in proportional increases in peak plasma concentrations. Similar to other glycopeptides, dalbavancin requires administration intravenously, as oral bioavailability is poor.³⁷⁶ One unique pharmacokinetic parameter associated with dalbavancin, documented in both adolescent and adult patients, is an elimination half-life of greater than 1 week, allowing for once-weekly dosing.^{53,325} The extended half-life of dalbavancin occurs as a result of substantial protein binding (approximately 95%) and intracellular retention.^{325,376} Only 33% of dalbavancin is excreted in the

urine unchanged; however, hepatic clearance does not appear to play an appreciable role in further drug metabolism.^{208,230,325} It remains unknown how the drug is further metabolized. Adult patients with significant renal impairment ($\text{CrCl} < 30 \text{ mL/min}$) have been shown to require dose reductions due to increased AUCs on dalbavancin.³²⁵ However, data from Marbury and colleagues suggest that patients on scheduled hemodialysis do not require dosage adjustment as they have levels of dalbavancin similar to those of patients with normal renal function.²³⁰ Like other glycopeptide antimicrobials, dalbavancin exhibits bactericidal activity against pneumococci and staphylococci, where the pharmacokinetic parameter associated with efficacy is ratio of 24-h AUC to MIC.^{13,325} In adult patients, dalbavancin is recommended as a two-dose regimen of 1000 mg in one dose to be followed a week later by a single dose of 500 mg, each administered via a 30-minute infusion.¹⁰⁶

Indications for use. Dalbavancin has been studied mainly in adult patients with skin and soft tissue infections. Jauregui and colleagues completed one phase III study of dalbavancin, administered as a single intravenous 1000-mg dose on day 1 followed by a 500-mg dose on day 8, versus linezolid, administered as a 600-mg intravenous or oral dose twice daily for 14 days, in adult patients with suspected or confirmed complicated skin and skin structure infections.¹⁷⁰ Patients were randomized in a 2:1 ratio to receive either dalbavancin or linezolid. Within this study cohort, *Staphylococcus aureus* was identified as at least one of the organisms causing infection in 89% of patients, with 51% of isolates reported as MRSA. The two-dose regimen of dalbavancin was found to be both well tolerated and as effective as a 14-day course of either oral or intravenous linezolid. Boucher and colleagues also completed a phase III trial in adult patients with acute bacterial skin and skin structure infections who were randomized into one of two arms of the study: dalbavancin, 1 g initially followed by 500 mg on day 8, or vancomycin, 1 g every 12 hours for 3 or more days, with the option to switch to oral linezolid to complete a 10- to 14-day course of therapy. Dalbavancin administered weekly was shown to be equally efficacious both early in therapy and at the end of therapy in individual and pooled analyses when compared to intravenous vancomycin followed by linezolid.⁴⁸ In older pediatric patients between 12 and 17 years of age, a phase I study of dalbavancin 1000 mg, the standard adult dose, or 15 mg/kg in those patients weighing less than 60 kg, resulted in similar terminal half-lives and plasma exposures between pediatric weight cohorts.⁵³ When compared to previous adult studies, the plasma exposure to dalbavancin was found to be slightly lower in pediatric patients. A phase I pharmacokinetics and safety trial is underway to evaluate a single-dose of dalbavancin in pediatric patients 3 months to 11 years of age. In this study, patients greater than 5 years of age received a dalbavancin dose of 15 mg/kg up to a dose of 1000 mg and patients less than 5 years of age received a dose of 25 mg/kg (NCT0194658). Other pediatric dalbavancin studies not yet recruiting participants include (1) a phase I study in neonates and infants up to 3 months of age assessing the safety and tolerability of a single dalbavancin dose of 22.5 mg/kg (NCT02688790) and (2) a phase III study in pediatric patients receiving dalbavancin or comparator agents (i.e., cefazolin, nafcillin, oxacillin, or vancomycin) for the treatment of acute hematogenous osteomyelitis. The dalbavancin dose to be used in this study is 15 mg/kg/dose, not to exceed 1500 mg in patients greater than 12 years of age and 1000 mg in patients less than 12 years of age (NCT02344511).

Adverse effects. Data from multiple trials indicate that dalbavancin is safe and well tolerated, with the majority of adverse events across studies reported as mild. During an initial phase I study of dalbavancin in adult patients, the most commonly reported adverse events included pyrexia, headache, and nausea.²⁰⁸ A phase I study in 10 pediatric patients also reported adverse events as mild, with the exception of one moderate event reported as headache.⁵³ Jauregui and colleagues found that gastrointestinal symptoms were the most common adverse events, whereas Boucher and colleagues found that adverse events occurred less frequently in those patients receiving dalbavancin versus the comparator group.^{48,170} Although multiple studies involving dalbavancin report a favorable adverse event profile, additional clinical experience with this agent will allow identification of the true rate of adverse events.

Daptomycin

Daptomycin is a cyclic lipopeptide derived from the fermentation of *Streptomyces roseosporus*. It has been approved for treatment of adults with complicated skin and soft tissue infections, endocarditis, and sepsis. It is a parenteral lipopeptide that disrupts cell membrane potential, and, unlike vancomycin, it is rapidly bactericidal against MRSA strains. Daptomycin demonstrates activity secondary to calcium-dependent insertion into the bacterial cell membrane resulting in rapid depolarization. This membrane depolarization results in cell death, without cell lysis, in a concentration-dependent manner. Daptomycin is active against *S. aureus* (including MRSA, MSSA, and GRSA), streptococci, and *Enterococcus* spp. This antibiotic is not effective for the treatment of pneumonia because it is inactivated by surfactant. Daptomycin demonstrates time-independent and nearly linear pharmacokinetics over a broad dosing range; increases in dosage result in proportional increases in the peak plasma concentration and AUC. This agent demonstrates high reversible protein binding, at 92%, and is primarily renally excreted with a half-life of approximately 8 to 9 hours. Renal dose adjustment is recommended with significant renal impairment (CrCl <30 mL/min).¹³⁴ Daptomycin is administered once daily. A retrospective review of 16 pediatric cases with invasive gram-positive bacterial infections (MRSA, $n = 14$; MSSA, $n = 1$; and VRE, $n = 1$) showed clinical improvement after the addition of daptomycin to conventional therapy in patients with persistent bacteremia and severe clinical disease.¹⁴ A pharmacokinetic analysis evaluated single-dose daptomycin for children 2 to 6 years of age. A dose of 8 to 10 mg/kg was shown to be well tolerated and reached appropriate systemic exposure, comparable to that in adults receiving doses of 4 to 6 mg/kg.¹ Single-dose pharmacokinetics were also evaluated in young infants, with a postnatal age range of 23 to 40 weeks, using a daptomycin dose of 6 mg/kg. Within this infant cohort, daptomycin was well tolerated with no reported adverse events, and clearance was found to be similar to that reported in children 2 to 6 years of age but faster than observed in adolescents/adults.⁸⁴ A retrospective, multicenter review of 46 pediatric patients treated with daptomycin for various gram-positive bacterial infections including sepsis (central venous catheter related, $n = 13$; non-central venous catheter related, $n = 7$), osteomyelitis ($n = 12$), complicated skin and soft tissue infections ($n = 11$), and endocarditis ($n = 3$) found that clinical cure occurred in 56.8%, clinical improvement in 29.6%, and failure in 13.6% of patients. Daptomycin was well tolerated with a median dose and duration of 7 mg/kg per day and 14 days, respectively.¹²⁷ Studies focusing on the inverse relationship between age and the required per-kilogram dose of daptomycin in children are ongoing. Side effects of daptomycin reported in adults include prolongation of prothrombin time and myopathy, with elevation of the serum creatinine kinase, which should be monitored weekly during treatment.

Colistin (Colistimethate Sodium: Polymyxin E)

Colistin is a cationic, cyclic polypeptide antibiotic that is structurally and pharmacologically related to polymyxin B. Colistin is less active in vitro and less toxic than is polymyxin B. Colistin was discovered in 1949 and is obtained from cultures of *Bacillus polymyxa* subsp. *colistinus*. The polymyxins have been used extensively for decades in topical ophthalmic and otic solutions. However, because of reports of common and serious nephrotoxicity and neurotoxicity, parenteral use of these drugs was abandoned in the early 1980s, except for treatment of multidrug-resistant, gram-negative bacterial infections in children and adults with cystic fibrosis. The emergence of gram-negative bacteria resistant to most classes of antibiotics and the lack of effective new antimicrobial agents led to the reconsideration of colistin as a valuable therapeutic option. Studies of patients who received intravenous polymyxins for the treatment of serious multidrug-resistant *P. aeruginosa* and *A. baumannii* infections, including pneumonia, bacteremia, and urinary tract infections, led to the conclusion that these antibiotics have acceptable effectiveness and considerably less toxicity than was reported previously.¹⁸⁵

Mechanisms of Action

Colistimethate sodium is inactive until it is hydrolyzed to sulfomethylated derivatives and colistin, which acts as a cationic detergent with both

lipophilic and lipophobic components. It damages the cytoplasmic membrane by displacing calcium and magnesium and binding to anionic lipopolysaccharide molecules, leading to permeability changes in the cell membrane, leakage of osmotically active intracellular metabolites and nucleosides, and cell death. Furthermore, colistin binds and neutralizes the lipid A portion of lipopolysaccharide in vitro; however, the clinical implications of this antiendotoxin activity are unknown.¹⁰⁹

Mechanisms of Resistance

Gram-negative bacteria can develop resistance to colistin by means of inherited or acquired mechanisms. Inherited mutations occur infrequently and are not influenced by exposure to colistin. Acquired resistance rarely may be induced by prolonged exposure to the drug. Studies of polymyxin-resistant *P. aeruginosa* suggest that the development of resistance arises from modifications of the cell membrane, such as reductions in lipopolysaccharide, certain proteins or lipids, or magnesium or calcium. Currently, no evidence of efflux pump or enzyme-mediated resistance exists. Complete cross resistance occurs between colistin and polymyxin B, but not other antimicrobial agents.

In Vitro Activity

Colistin is highly active against many strains of aerobic gram-negative bacteria, including *Acinetobacter*, *Citrobacter*, *E. coli*, *Enterobacter*, *H. influenzae*, *Klebsiella*, *Morganella morganii*, *P. aeruginosa*, *Salmonella*, *Shigella*, and variable numbers of *Stenotrophomonas* strains. However, the antibiotic is inactive against most strains of *Brucella*, *Burkholderia cepacia*, *Edwardsiella*, *Proteus*, *Providencia*, *Serratia*, gram-negative cocci, gram-positive bacteria, and anaerobic bacteria. The CLSI defined bacterial resistance to colistin as an MIC of 4 µg/mL or greater. However, the sulfate form of colistin, which usually is used for in vitro testing, often is fourfold to eightfold more active than the sulfomethyl form, which is used in the parenteral formulation. Limited in vitro and clinical data suggest that synergism exists with colistin and other antimicrobial agents such as aminoglycosides, antipseudomonal β-lactams, fluoroquinolones, rifampin, and TMP-SMX.^{109,185}

Pharmacokinetics

The pharmacologic evaluation of the polymyxins was performed decades ago. Consequently, pharmacokinetic and pharmacodynamic information is limited. Colistin is not absorbed from the gastrointestinal tract and must be given parenterally. The drug is distributed widely in the body, except for bones and synovial, pleural, and pericardial fluids. In a reported case of multidrug-resistant *A. baumannii* meningitis in an adolescent, parenterally administered colistin achieved a concentration in the CSF that was 25% of the serum concentration, and it cured the infection.¹⁷² More than 50% of the agent binds to serum proteins. Colistimethate sodium and its metabolites are excreted mainly by the kidneys through glomerular filtration. Therefore, the dosage and frequency of administration should be decreased in children with renal impairment. Colistin is rapidly bactericidal against susceptible bacteria in a concentration-dependent manner, and it has a postantibiotic effect.^{109,185} Considering these pharmacologic parameters, there may be a theoretical benefit in administering colistin less frequently with higher doses, but no clinical data validate this hypothesis.

Indications for Use

Colistin has been administered intravenously to infants and children of all ages for the treatment of acute or chronic infections caused by susceptible gram-negative organisms, particularly multidrug-resistant strains of *Pseudomonas* and *Acinetobacter* in patients with cystic fibrosis or complicated health care-associated infections. Colistin should be reserved for use when other more effective and less toxic antimicrobial agents are contraindicated or ineffective. The dosage of colistimethate sodium is expressed in terms of colistin. The usual parenteral dosage for adults and children with normal renal function is 2.5 to 5 mg/kg (75,000 to 150,000 IU/kg)/day divided into two to four doses, depending on the severity of infection (maximum, 300 mg/day). Intramuscular administration is not recommended because it causes severe pain at the injection site. Experience with the use of colistimethate sodium administered by nebulization for multidrug-resistant, gram-negative

respiratory infections in patients with cystic fibrosis is extensive. Successful use of colistimethate sodium by the intraventricular route also has been reported. Colistin sulfate in combination with neomycin sulfate and hydrocortisone acetate is available in the United States for otic use. Colistin sulfate for oral administration no longer is available in the United States. Polymyxin B sulfate is available for topical use.¹⁰⁹

Adverse Effects

Nephrotoxicity and neurotoxicity are the most serious adverse effects and occur most frequently when the drug is administered in higher than recommended doses, in patients with renal insufficiency, or in combination with other nephrotoxic agents. Progressive azotemia or acute tubular necrosis may occur, but renal dysfunction usually is reversible when the antibiotic is discontinued. Renal function should be monitored closely during therapy, and colistin should be discontinued immediately if urine output diminishes or concentrations of blood urea nitrogen or creatinine increase. Transient effects on the nervous system may occur, including dizziness, weakness, paresthesia, numbness, vertigo, ataxia, blurred vision, and slurred speech, but these symptoms are reversible and may be alleviated by reducing the dosage of colistin. Coma, psychosis, seizures, and noncompetitive neuromuscular blockade causing apnea also have been reported and warrant prompt discontinuation of the drug.

AGENTS THAT TARGET PROTEIN SYNTHESIS

Aminoglycosides

Aminoglycosides are natural and semisynthetic compounds that consist of at least two amino sugars bound by a glycosidic linkage to a hexose nucleus, the aminocyclitol ring. Streptomycin, isolated from *Streptomyces griseus*, was the first aminoglycoside and was available for use in 1944. Many aminoglycosides have been isolated or developed since that time. The suffix denotes the origin of the aminoglycoside—those ending with the suffix *mycin* were derived from *Streptomyces* spp., whereas those ending with *micin* were derived from *Micromonospora* spp. Currently, seven aminoglycosides are available for use in the United States (Table 236.3), and several more are available in other countries. Despite the development of less toxic antibiotics with broad-spectrum activity, aminoglycosides continue to fulfill an essential role in the treatment of severe infections caused by aerobic gram-negative bacilli and enterococci.

Mechanisms of Action

Against susceptible bacteria, aminoglycosides demonstrate rapid, concentration-dependent bactericidal activity.^{105,357} They exert their effect by binding irreversibly to the 30S subunit of the bacterial ribosome, which results in inhibition of protein synthesis and induction of translational errors. Bacterial uptake of aminoglycosides can be facilitated by concomitant therapy with cell wall-active antibiotics such as β -lactams or vancomycin. Penetration of the outer membrane of gram-negative bacteria is mediated by a self-promoted uptake process involving aminoglycoside-induced disruption of magnesium bridges between adjacent lipopolysaccharide molecules. Passage through porin channels is unlikely because of the large size of aminoglycosides. Subsequent transport into cytoplasm and attachment to the 30S ribosomal subunit

require two energy- and oxygen-dependent steps, energy-dependent phases I and II (EDPI and EDPII), that use an electrochemical proton gradient. EDPI is inhibited by hyperosmolarity, low pH, and anaerobic conditions. Unlike other protein synthesis inhibitors, which usually are bacteriostatic, aminoglycosides are bactericidal. Binding of aminoglycosides to the 30S subunit does not prevent formation of the initiation complex of peptide synthesis. However, it disrupts elongation of the peptide chain by impairing the proofreading process, an impairment that results in translational inaccuracy. Aberrant protein products may be inserted in the cell membrane and cause altered permeability. The primed amino sugar and 2-deoxystreptamine groups are essential for the ribosome-specific activity of aminoglycosides.²⁴⁰

Mechanisms of Resistance

The prevalence of acquired aminoglycoside resistance is relatively low, and its development during therapy is an unusual event. Bacteria can acquire resistance to aminoglycosides because of alterations in the bacterial target, reduced bacterial cell permeability or uptake, or modification of the antibiotic by bacterial enzymes, the last being most significant clinically.⁹⁶ Mutations in the aminoglycoside-binding site of the 30S ribosome have been associated with high-level resistance to streptomycin but not to other aminoglycosides, possibly because, unlike in streptomycin, they bind to multiple sites on the ribosome. Facultative aerobic bacteria causing infection in sites with reduced oxygen tension, anaerobic bacteria, and such fermentative bacteria as streptococci are inherently resistant to aminoglycosides because they are unable to generate an electrochemical proton gradient sufficient for aminoglycoside transport into the cytoplasm. Other bacteria can acquire resistance because of reduced permeability or lack of transport, as demonstrated in staphylococci, in which resistance to aminoglycosides quickly develops when monotherapy is administered. *P. aeruginosa*, other nonfermenting gram-negative bacilli, and, less frequently, members of the Enterobacteriaceae can acquire a moderate level of resistance to all aminoglycosides as a result of various mechanisms that interfere with uptake, cytoplasmic transport, or regulation of the anaerobic respiratory pathway. Plasmid-mediated production of aminoglycoside-modifying enzymes is the most common mechanism of acquired resistance. Many enzymes have different substrate specificities, several of which can be elaborated simultaneously in the same bacterium. These acetyltransferases, nucleotidyltransferases, and phosphotransferases interact with amino or hydroxyl groups on the aminoglycoside and modify the aminoglycoside so that it binds poorly to the 30S ribosome, thereby usually resulting in high-level resistance.²⁴⁰ Gentamicin and tobramycin are each susceptible to at least five modifying enzymes, whereas amikacin possesses an aminohydroxybutyryl group that prevents enzymatic modification at multiple sites. Consequently, more than 80% of gentamicin-resistant strains of Enterobacteriaceae and 25% to 85% of gentamicin-resistant *P. aeruginosa* strains are susceptible to amikacin.¹⁹⁹

In Vitro Activity

The in vitro antibacterial spectrum of aminoglycosides includes a wide range of aerobic gram-negative bacilli, many oxacillin-susceptible staphylococci, many enterococci, and some mycobacteria.²⁴² Some gram-negative bacilli, including *B. cepacia* and *S. maltophilia*, are consistently resistant to all aminoglycosides. The spectra of activity of gentamicin and tobramycin are similar, and strains resistant to one usually are resistant to the other. The major advantage of tobramycin currently is its activity against some strains of *Acinetobacter* and indole-positive Proteae (*Morganella* spp., *Proteus* spp., *Providencia* spp.) that are resistant to gentamicin.²⁹³ Because many aminoglycoside-modifying enzymes are active against gentamicin and tobramycin but inactive against amikacin, amikacin frequently is prescribed for empirical treatment of nosocomial gram-negative bacillary infections. Amikacin also has activity against the *Mycobacterium avium* complex (MAC), some rapidly growing mycobacteria, and *Nocardia asteroides*. Although gentamicin, tobramycin, and amikacin have similar spectra of activity, susceptibility testing is recommended because of geographic and interhospital variation in resistance patterns. Lack of activity against *P. aeruginosa*, *Klebsiella*, and *Serratia* has limited the use of kanamycin, which is no longer available in the United States. Streptomycin is inactive

TABLE 236.3 Classification Scheme for Aminoglycosides

Aminocyclitol Ring	Family	Member
Streptidine	Streptomycin	Streptomycin
2-Deoxystreptamine	Kanamycin	Kanamycin Amikacin Tobramycin
2-Deoxystreptamine	Gentamicin	Gentamicin
2-Deoxystreptamine	Neomycin	Neomycin Paromomycin

against many gram-negative enteric bacilli but does have activity against *Francisella tularensis*, *Yersinia pestis*, and *Mycobacterium tuberculosis*.

Pharmacokinetics

Aminoglycosides have in common many pharmacokinetic characteristics. They are highly polar, water-soluble compounds that are positively charged cations at neutral pH. Their antibacterial activity is pH dependent, with increased activity at higher pH. They are relatively resistant to degradation at various temperatures and pH values. After parenteral administration, aminoglycosides are distributed rapidly in extracellular body water, with slow accumulation in tissues. The volume of distribution is decreased (with respect to total body weight) in obese patients and is increased in patients with illnesses associated with edema, such as severe infections, burns, congestive heart failure, and ascites. With the exception of proximal renal tubular cells and possibly inner ear hair cells, penetration into other body compartments is impaired because of lipid insolubility, polycationic charge, and size of the aminoglycoside. Proximal renal tubular cells absorb aminoglycosides through carrier-mediated pinocytosis, and, as a result, renal cortical concentrations exceed those in plasma. Aminoglycosides do not penetrate the blood-brain barrier in the absence of meningeal inflammation, but with inflammation, approximately 20% to 25% of the serum concentration penetrates the CSF. These CSF concentrations are low in relation to the MIC of the meningeal pathogen for which it is given. Thus, because of this narrow therapeutic-toxic index, monotherapy for gram-negative bacillary meningitis with aminoglycosides is not recommended. Aminoglycosides are not metabolized and, after parenteral administration, are excreted unchanged in the kidney by glomerular filtration, with approximately 5% of excreted drug reabsorbed in the proximal tubular cells. Minimal amounts are excreted in saliva and feces. Urine concentrations exceed those in plasma by 25 to 100 times.

After intramuscular injection, aminoglycosides are absorbed completely, and peak serum concentrations are achieved within 90 minutes, except in some disease states that interfere with tissue perfusion, such as hypotension. When administered intravenously, the infusion should be given slowly over the course of 30 to 60 minutes to avoid the development of potential adverse effects. Peak serum concentrations are achieved within 30 to 60 minutes after infusion. Because of the polar nature of these drugs, absorption after oral administration is insignificant and inadequate to treat systemic infections, but aminoglycosides can accumulate in the presence of renal failure and result in concentrations sufficient to cause toxicity. Although aminoglycosides are nonirritating when they are instilled into pleural or peritoneal spaces, their absorption is rapid and can result in significant toxicity. In contrast, instillation into the lateral ventricles or irrigation of the bladder has not been associated with significant systemic absorption. In contrast to parenteral administration, aerosol administration of aminoglycoside results in higher concentrations in bronchial secretions and less toxicity.²⁸⁹ Indiscriminate use of topical aminoglycosides in the form of ointments, creams, or ophthalmic solutions may lead to the rapid development of aminoglycoside resistance, especially in immunocompromised patients.

Antimicrobial dosing in newborns and young infants differs from that in older children and adults because of developmental changes in renal function and increased total body water composition. Neonates and young infants have a larger volume of distribution and a reduced glomerular filtration rate; these differences are more pronounced in premature neonates with very low birth weight.²⁸² Therefore, once- to twice-daily regimens have been the standard of care in newborn infants for years. Once-daily gentamicin dosing of 4 mg/kg in term neonates has been studied extensively and is used routinely in many nurseries; no differences in effectiveness or toxicity have been observed.³⁵⁷ The aminoglycoside dosing schedule currently approved for use in older infants and children is a three-times-daily regimen. Because aminoglycosides demonstrate concentration-dependent bactericidal activity, higher peak serum concentrations result in more extensive and more rapid killing.³⁵⁷ Aminoglycosides also demonstrate a postantibiotic effect against susceptible aerobic gram-negative bacilli in vitro and in vivo.³⁷⁸ Furthermore, host leukocytes display enhanced phagocytosis of aminoglycoside-exposed bacteria in vitro, referred to as *postantibiotic leukocyte enhancement*.¹¹⁷ The higher the peak serum concentration,

the longer the duration of the postantibiotic effect. In the presence of normal renal function, the serum concentration is low or undetectable before the administration of the next dose (trough value), but antibacterial activity persists because of the postantibiotic effect. These characteristics favor single-daily dosing. Numerous studies in adults have shown that once-daily dosing of aminoglycosides (i.e., amikacin, gentamicin, or tobramycin) is either equivalent or superior to multiple-daily dosing with regard to clinical and bacteriologic effectiveness, nephrotoxicity, ototoxicity, mortality, and cost effectiveness.³⁵⁷ The Hartford nomogram originally described by investigators from Hartford, Connecticut, commonly is used to guide extended-interval aminoglycoside dosing for adults. In adults, a single serum concentration of gentamicin or tobramycin is obtained 8 to 12 hours after the start of the infusion of the first dose and plotted on the nomogram to determine the appropriate dosing interval.¹²² Similar nomograms for children have not been validated. Nonetheless, published guidelines support 7.5 mg/kg per dose of gentamicin for infants and children up to 10 years of age; for adolescents and adults, 6 to 7 mg/kg per dose is appropriate.^{88,357} Extended-interval aminoglycoside dosing is contraindicated if the patient's volume status is altered (e.g., third spacing, thermal injury >20% total body surface area), if optimal dosing regimen is predefined (e.g., in cystic fibrosis and endocarditis), if renal function is impaired, or if immune status is compromised.

Indications for Use

The major use of aminoglycosides in children (usually in combination with other antibacterial agents) is for serious infections caused by gram-negative enteric bacilli, including neonatal sepsis, sepsis in a child with malignant disease or an immunologic defect, abdominal and systemic infections associated with spillage of fecal contents into the peritoneum, endocarditis caused by certain susceptible bacteria, and complicated urinary tract infections. Because gentamicin is the least expensive aminoglycoside and the one with which physicians have the most experience, it often is considered the first-line agent for empirical treatment of suspected aerobic gram-negative bacillary infections in institutions with minimal background resistance. Combinations of an aminoglycoside and a cell wall-active antibiotic have been used for synergistic bactericidal activity. Gentamicin or streptomycin, in combination with penicillin G, ampicillin, or vancomycin, is recommended for the treatment of endocarditis caused by susceptible enterococci, viridans streptococci, or *Streptococcus bovis*. Administration of gentamicin for 3 to 5 days, in combination with an antistaphylococcal agent, should be considered for the treatment of staphylococcal endocarditis.²² An aminoglycoside combined with an acylureidopenicillin, ceftazidime, cefepime, or a carbapenem may be considered for serious infections suspected to be caused by *P. aeruginosa* or other gram-negative pathogens pending susceptibility data. Amikacin often is used for empirical treatment of nosocomial aerobic, gram-negative bacillary infections in patients in institutions having significant resistance to gentamicin and tobramycin. Streptomycin is indicated for use alone or in combination with other antibiotics for the treatment of tularemia and plague and in combination with other agents for the treatment of tuberculosis, brucellosis, and enterococcal endocarditis. For such purposes, gentamicin could be a more suitable agent for some of these conditions, such as brucellosis, tularemia, and plague. Paromomycin is too toxic for parenteral use, but when administered orally, it has been useful in the treatment of asymptomatic intestinal amebiasis, *Dientamoeba fragilis* infection, and *Giardia lamblia* infection during pregnancy. Tobramycin inhalation solution is approved by the FDA for twice-daily dosing in patients with cystic fibrosis.

Adverse Effects

Although aminoglycosides have intrinsic toxicity, allergic reactions are uncommon. All aminoglycosides can injure the proximal renal tubules, the cochlea, the vestibular apparatus, or a combination thereof and can cause neuromuscular blockade, but the risk varies with each agent. Because aminoglycosides do not induce a significant inflammatory response, pain at intramuscular injection sites and phlebitis at intravenous infusion sites are unusual. Hypersensitivity reactions and drug fever are rare events.

Many theories have been postulated regarding the mechanism of nephrotoxicity,²⁴¹ including inhibition of lysosomal phospholipases within the proximal renal tubules. Clinical findings include a mild, nonoliguric decrease in the glomerular filtration rate that typically is reversible. In contrast to traditional dosing, once-daily dosing causes similar or lower rates of nephrotoxicity.^{88,357} In humans, nephrotoxicity has been associated with prolonged duration of therapy at high dosages, previous aminoglycoside therapy, administration of drugs to critically ill patients with intravascular volume depletion or hyponatremia and to those with impaired kidney function, and concomitant administration of other potentially nephrotoxic agents such as amphotericin B and loop diuretics.⁹⁸

The mechanism by which aminoglycosides cause vestibular and cochlear ototoxicity has not been elucidated fully. Cochlear damage is manifested as tinnitus or high-frequency hearing loss, whereas vestibular toxicity is associated with vertigo, nystagmus, and ataxia.¹⁸ Damage can be unilateral or bilateral. Occasionally, the ototoxicity is reversible, but permanent damage occurs commonly. Mild cochlear damage may not be recognized because the high-frequency hearing range is affected first. Conventional audiograms that do not test high-frequency ranges may not detect cochlear injury. Delayed onset of high-frequency hearing loss has been observed in humans. Factors that increase the risk for development of aminoglycoside ototoxicity in humans include impaired renal function and prolonged duration of treatment. Neuromuscular blockade can occur after rapid intravenous infusion, after extensive peritoneal irrigation, or during routine parenteral aminoglycoside administration in patients with underlying conditions that affect the neuromuscular junction, such as myasthenia gravis and botulism, or during concomitant administration of agents that act on the neuromuscular junction, such as succinylcholine. Hypomagnesemia in the neonate may predispose to hearing loss.

To avoid toxicity and ensure therapeutic values, concentrations of aminoglycosides in serum should be monitored in all patients who have impaired renal function or who receive other nephrotoxic medications or prolonged treatment; such monitoring is particularly relevant to preterm, low-birth-weight infants. Monitoring also should be considered in obese and undernourished children, children with severe burns, and those with chronic disease, for which the volume of distribution of the drug can be altered (e.g., cystic fibrosis).

Macrolides

Erythromycin, isolated from *Streptomyces erythreus* found in a soil sample in the Philippines, was the first macrolide and was available for use in 1952. Many natural and semisynthetic erythromycin derivatives have been developed since then, three of which are approved for use in pediatrics: erythromycin, clarithromycin, and azithromycin. Macrolide antibiotics consist of a large lactone ring attached by a glycosidic bond to one or more amino or neutral sugar moieties. Erythromycin and clarithromycin have 14-member lactone rings, whereas azithromycin, an azalide antibiotic that is grouped with the macrolides, has a tertiary amino group inserted in its 15-member ring. In addition to similarities in chemical structure, these macrolides have similar antibacterial spectra, mechanisms of action, and mechanisms of resistance, but they differ in their pharmacokinetic characteristics. Ketolides are a new class of macrolides with in vitro activity against macrolide-resistant gram-positive organisms, including *S. pneumoniae*. Telithromycin received FDA approval in 2004 for use in adults, but use is limited to mild-to-moderate community-acquired pneumonia after increasing reports of hepatotoxicity.³⁸⁴

Mechanisms of Action

Macrolide antibiotics reversibly bind to the 50S ribosomal subunit and inhibit protein synthesis. Initial studies suggested that the antibacterial activity of erythromycin usually was bacteriostatic, but against some actively growing, susceptible bacteria, large concentrations of erythromycin were bactericidal.¹⁴⁶ Clarithromycin and azithromycin usually are bacteriostatic, but they are bactericidal against *S. pyogenes*, *S. pneumoniae*, and *H. influenzae*.³⁸⁵ Macrolides cause dissociation of peptidyl-tRNA from bacterial ribosomes, which results in accumulation of intracellular peptidyl-tRNA and depletion of the free tRNA pool,

with toxic effects for bacteria.³⁴⁴ The specific target appears to be the 23S ribosomal RNA. Macrolides block the entrance to the tunnel in the 50S ribosomal subunit through which many, if not all, nascent peptide chains exit the ribosome. By blocking the exit tunnel, macrolides induce premature dissociation of peptidyl-tRNAs from the ribosome just after initiation of protein synthesis. Erythromycin interferes with binding to the 50S ribosome by chloramphenicol and clindamycin, thus suggesting common or overlapping binding sites for these agents.

Mechanisms of Resistance

Many gram-negative bacteria are inherently resistant to macrolides because of the relative impermeability of their outer membrane. Other bacteria can acquire resistance by production of enzymes that modify and inactivate the macrolide, active efflux of the antibiotic, and alteration of their ribosomal targets.²⁰⁶ Two mechanisms by which bacteria can alter their ribosomes and acquire macrolide resistance have been identified. High-level resistance because of an altered protein component in domain V of the 50S ribosomal subunit has occurred after a one-step chromosomal mutation. Such resistance has been demonstrated in *M. avium*, *Helicobacter pylori*, *Treponema pallidum*, and *Propionibacterium* spp. Plasmid-mediated macrolide, lincosamide, and streptogramin B (MLS_B) resistance occurs when a single adenine residue within a conserved region of domain V of the nascent 23S rRNA component of the 50S ribosomal subunit is methylated. Such methylation results in an altered common target that confers cross resistance to macrolides (i.e., erythromycin and clarithromycin), azalides (i.e., azithromycin), lincosamides (i.e., clindamycin), and streptogramin B (i.e., quinupristin-dalfopristin).²⁰⁶ The production of methylases is encoded by a class of genes referred to as *erm* (erythromycin ribosome methylation), approximately 40 of which have been characterized in a wide range of microorganisms, including gram-positive species, spirochetes, and anaerobes. Twenty-one classes of *erm* genes with less than 80% sequence homology have been designated unique letters. Pathogenic bacteria are one of four major classes: bacteria in classes *erm*(A) and *erm*(C) typically are in methicillin-resistant or methicillin-susceptible strains of staphylococci, respectively; members of class *erm*(B) are mostly in streptococci and enterococci; and class *erm*(F) usually is associated with anaerobic pathogens.²⁹⁹ These genes are exchanged easily among different strains by plasmids, transposons, or bacterial conjugation. Resistance mediated by *erm* can be constitutive or inducible. When bacteria with inducible MLS_B resistance are exposed to a macrolide inducer (i.e., erythromycin, clarithromycin, or azithromycin), inactive methylase mRNA undergoes rearrangements that permit ribosomes to translate the methylase coding sequence. The diversity of inducible macrolide-resistant genotypes results in complex phenotypes, particularly among streptococci and enterococci with *erm*(B) genes, whereas constitutive production of a methylase generally confers a predictable high-level cross resistance to all MLS_B antibiotics. Staphylococci that are resistant in vitro to 14- and 15-membered ring macrolides but susceptible to 16-membered ring macrolides, clindamycin, and streptogramins B should routinely undergo further testing with a double-disk diffusion test to screen for an erythromycin-induced, "D"-shaped zone of bacterial inhibition around a clindamycin disk. A positive D-test indicates that the *Staphylococcus* isolate has inducible MLS_B resistance and that use of clindamycin can result in clinical treatment failure, presumably related to selection of constitutive mutants in patients with severe infections and large bacterial inocula.²⁰⁶ Similar inducible resistance phenotypes may be observed among various strains of streptococci for which the use of clindamycin should be discouraged.

Macrolide resistance associated with active efflux is caused by two classes of pumps: a plasmid-mediated, ATP-binding cassette (ABC) transporter encoded by the *msr*(A) gene and found in *Staphylococcus* spp., and a protein of the major facilitator superfamily found in streptococci and enterococci and encoded by the *mef*(A) gene. The MsrA pump confers a macrolide and streptogramin B (MS_B) pattern of resistance that can be distinguished from the MLS_B-inducible phenotype by the double-disk diffusion D-test. The Mef(A) pump affects only 14- and 15-membered ring macrolides (M phenotype).²⁰⁶ Less commonly, bacteria produce enzymes that inactivate macrolides, including acetyltransferases, esterases, phosphotransferases, or glycosylases

found in some strains of Enterobacteriaceae, but macrolides are not used to target these pathogens. Therefore, this mechanism of low-level resistance is not clinically important.²⁹⁹ A causal association between erythromycin resistance and antibiotic use, probably mediated by selection pressure, was suggested by a nationwide epidemiologic study in Finland in which reduction of the use of erythromycin over the course of time was associated with a steady decline in erythromycin resistance among *S. pyogenes* isolates from throat swabs and pus specimens.³²¹ Conversely, increased consumption of macrolides in Spain since 1995 was related to an increase in macrolide resistance.¹³⁷ Pneumococcal resistance to macrolides has also increased to about 35% as reported in prospective multicenter monitoring studies. In the United States, 6% of the macrolide-resistant isolates exhibited low-level erythromycin resistance by expression of the *mef(A)* gene and about 20% expressed the *mef(A)* and the *erm(B)* gene, resulting in high-level resistance.^{171,384}

In Vitro Activity

Erythromycin is effective in vitro against a diverse group of microorganisms, including *Bacteroides* spp., *Bordetella pertussis*, *Chlamydomphila* spp., *Corynebacterium diphtheriae*, *H. pylori*, the bacterium of Legionnaires disease (*Legionella pneumophila*), mycoplasmas (*Mycoplasma pneumoniae* and *Ureaplasma urealyticum*), spirochetes (*T. pallidum*), and anaerobic and aerobic gram-positive cocci (*S. pneumoniae*, *S. pyogenes*, and penicillinase-producing and non-penicillinase-producing strains of oxacillin-susceptible *S. aureus*). Erythromycin is active against *Campylobacter jejuni*, *N. meningitidis*, *N. gonorrhoeae*, and, to a lesser extent, *H. influenzae*. Macrolide resistance among diverse pathogens is increasing worldwide, and the clinical consequences are topics of active research.^{128,166,197}

The newer macrolides have spectra of activity similar to that of erythromycin. In contrast to erythromycin, clarithromycin has equivalent or greater activity against *M. catarrhalis*, *H. influenzae*, *M. pneumoniae*, *Chlamydia pneumoniae*, *Chlamydia trachomatis*, *L. pneumophila*, *U. urealyticum*, and *N. gonorrhoeae*. Clarithromycin is two to four times more active against most erythromycin-susceptible streptococci and staphylococci. However, pneumococci that are resistant to erythromycin ($\leq 48\%$ in certain regions¹⁹⁵) also are resistant to clarithromycin and azithromycin; rates of macrolide resistance among pneumococci tend to correlate with rates of penicillin resistance.³⁸⁵ Clarithromycin also has activity against organisms that are resistant to erythromycin, including *H. pylori*, *Toxoplasma gondii*, *Mycobacterium leprae*, MAC, and *Mycobacterium chelonae*.

In contrast to erythromycin, azithromycin has less activity against gram-positive bacteria, including *S. pneumoniae*, but has better activity against gram-negative bacteria, including *Vibrio cholerae* and some Enterobacteriaceae such as *Shigella* spp. The in vitro activity of azithromycin against *M. pneumoniae*, *C. pneumoniae*, and *L. pneumophila* is similar to that of erythromycin and clarithromycin. Azithromycin is more active than erythromycin against *C. trachomatis* and *U. urealyticum* and twofold to eightfold more active than erythromycin or clarithromycin against *M. catarrhalis*, *H. influenzae*,^{23,237} *N. gonorrhoeae*, and *H. ducreyi*. Azithromycin has activity against *T. gondii* and, although less than that of clarithromycin, against MAC organisms. Azithromycin and clarithromycin are highly effective in vitro against *Borrelia burgdorferi*, *Bartonella henselae*, and *Bartonella quintana*.

Pharmacokinetics

The macrolides differ in pharmacokinetic properties. Clarithromycin¹⁴⁴ and azithromycin¹³⁵ are gastric acid stable and relatively well absorbed from the gastrointestinal tract, whereas erythromycin is acid labile and absorption varies with the oral preparation. Macrolides undergo metabolism by the hepatic microsomal cytochrome P450 (CYP450) system. Erythromycin and clarithromycin, but not azithromycin, are inhibitors of the CYP450 enzyme system (CYP3A and CYP1A subclasses) and can interact with other drugs that are metabolized by this system.²⁷¹ Most of the metabolites are inactive, with the exception of 14-(R)-hydroxylclarithromycin, an active metabolite that can act additively or synergistically with clarithromycin. The lipophilic macrolides are distributed well in tissues and fluids, except CSF. High intracellular

concentrations are achieved, but, with the exception of azithromycin, the macrolides rapidly diffuse out of cells when extracellular concentrations are low. Clarithromycin and azithromycin are transported actively into leukocytes and macrophages. High concentrations of clarithromycin are present in the nasal mucosa, tonsils, and pulmonary epithelial lining fluid and alveolar cells.⁸⁷ Tissue concentrations of clarithromycin and azithromycin exceed those found in plasma by 2 to 20 times and 10 to 100 times, respectively. The favorable cellular penetration probably contributes to the efficacy of clarithromycin and azithromycin in the treatment of intracellular pathogens. Furthermore, sustained intracellular concentrations of azithromycin facilitate short-course therapy for pharyngitis and acute otitis media and single-dose therapy for chlamydial STDs.¹³⁵ Isolated cases of intravascular bacterial infections developing during macrolide therapy for focal infections have been reported and evoke concern that, despite elevated tissue concentrations, low serum concentrations may not treat systemic infections consistently.¹⁹⁷ Erythromycin and azithromycin are eliminated primarily by biliary excretion, whereas clarithromycin is excreted predominantly by the kidneys. A reduction in the dosage of clarithromycin may be required in patients with moderate-to-severe renal insufficiency. Because of their longer serum half-life, azithromycin and clarithromycin can be administered in a once- and twice-daily regimen, respectively, in contrast to the three- or four-times-daily dosing necessary for erythromycin.

Because erythromycin base is unstable at the low pH of the stomach, better-absorbed products were prepared by the addition of protective enteric coating or by alteration of the chemical structure through the formation of salts and esters. Salt and ester derivatives include ethylsuccinate or propionate (esters), stearate (a salt), and estolate (salt of an ester). Estolate provides the highest concentration of antimicrobial activity in serum, but controversy continues about which preparation provides the most biologically active drug at the site of infection. Because the base is the active component, all erythromycin preparations must be hydrolyzed to the base after absorption. Formulations of erythromycin base include tablets, delayed-release tablets, and capsules. Erythromycin estolate is marketed in capsule form, suspension, and tablets. Erythromycin ethylsuccinate is available in suspension, tablets, and chewable tablets. Erythromycin stearate is in tablet form only in the United States. Parenteral preparations of erythromycin include the lactobionate and gluceptate derivatives. Intramuscular administration of these forms is painful and should be avoided. Clarithromycin can be taken without regard to food, whereas azithromycin should be taken at least 1 hour before or 2 hours after a meal. Clarithromycin is available in suspension (125 and 250 mg/5 mL) and in tablet (250 and 500 mg) forms. Azithromycin is manufactured in 250-mg tablets and as a suspension (100 and 200 mg/5 mL). Azithromycin for intravenous injection has not been approved for use in children younger than the age of 16 years, although pharmacokinetic data are available.¹⁶⁷

Indications for Use

Erythromycin is approved for the treatment of chlamydial conjunctivitis, pneumonia and urethritis, mycoplasmal and *Legionella* pneumonia, group A streptococcal sinusitis and pharyngitis, mild pneumococcal pneumonia, uncomplicated skin and soft tissue infections caused by susceptible organisms, diphtheria, pertussis, erythrasma, listeriosis, and nongonococcal urethritis and as second-line therapy for gonococcal urethritis. It also is approved for use as a preoperative bowel preparation, for penicillin-allergic persons as prophylaxis for bacterial endocarditis and rheumatic fever, and for the treatment of syphilis in nonpregnant individuals. In the context of increasing prevalence of erythromycin resistance among common pathogens, newer macrolides or other classes of antibacterial agents may be more effective for certain infections.

Clarithromycin is approved for treatment of bacterial exacerbations of bronchitis; streptococcal pharyngitis; mycoplasmal, chlamydial, and pneumococcal community-acquired pneumonia; acute maxillary sinusitis; and uncomplicated skin and soft tissue infections caused by susceptible bacteria. However, increasing rates of clarithromycin resistance among common pathogens of the respiratory tract and skin structures have been associated with treatment failure.^{123,166} Clarithromycin and amoxicillin or metronidazole in combination with bismuth compounds, H₂-receptor antagonists, or proton pump inhibitors is recommended

for the treatment of *H. pylori*-associated peptic ulcer disease. Clarithromycin also is approved for prophylaxis of disseminated MAC infections in children and adults with advanced human immunodeficiency virus (HIV) infection. Furthermore, clarithromycin, in combination with other antimycobacterials, is an effective therapeutic agent for disseminated MAC infections, but safety has not been established for this indication in children younger than 20 months of age. The safety and efficacy of clarithromycin have not been established for infants younger than 6 months of age.

In adults, azithromycin is approved for treatment of bacterial exacerbations of bronchitis; chlamydial and gonococcal cervicitis and urethritis; chancroid; streptococcal tonsillitis and pharyngitis; uncomplicated skin and soft tissue infections caused by susceptible bacteria; and acute otitis media and pneumonia caused by *H. influenzae*, *M. catarrhalis*, and *S. pneumoniae*. It also is approved in adults for prophylaxis of disseminated MAC infection in patients with advanced HIV infection. Pediatric indications include group A streptococcal pharyngitis; acute otitis media caused by *H. influenzae*, *M. catarrhalis*, and *S. pneumoniae*; and mild community-acquired pneumonia caused by *S. pneumoniae*, *H. influenzae*, *M. pneumoniae*, or *C. pneumoniae*.

Five-day regimens have been approved for the treatment of pharyngitis (single dose of 12 mg/kg per day followed by 6 mg/kg per day) and otitis media (single dose of 10 mg/kg followed by 5 mg/kg per day). A randomized clinical trial comparing azithromycin with high-dose (90/6.4 mg/kg per day) amoxicillin-clavulanate for the treatment of acute otitis media revealed that the lactam-containing regimen achieved superior bacteriologic and clinical outcomes for all bacterial pathogens, including penicillin-resistant *S. pneumoniae* and *H. influenzae*.¹⁵² Consequently, consensus guidelines do not recommend azithromycin or clarithromycin for empirical treatment of acute otitis media unless the patient has a type 1 hypersensitivity reaction to penicillins.¹¹ Shorter courses of azithromycin for uncomplicated group A streptococcal pharyngitis (20 mg/kg per day for 3 days)⁸² or acute otitis media (single dose of 30 mg/kg)¹⁶ have been found to be as effective as standard therapy but have not been approved by the FDA. A clinical study suggested that a 5-day course of azithromycin for localized cervical lymphadenopathy caused by *B. henselae* (cat scratch disease) is beneficial.²⁹ The CDC recommends azithromycin for the treatment of chlamydial genital infections, nongonococcal urethritis, and chancroid (a single 20-mg/kg dose; maximum dose, 1 g)³⁷⁰ and for prophylaxis of disseminated MAC infection in HIV-infected children.⁷³ The American Thoracic Society and Infectious Disease Society of America guidelines for treatment and prevention of nontuberculous mycobacteria recommend a combination regimen including a macrolide (either clarithromycin or azithromycin) with ethambutol and rifampin for patients with nodular, bronchiectatic, or fibrocavitary lung disease caused by MAC.¹³⁹ Data supporting the use of azithromycin for treatment of ophthalmia neonatorum caused by *C. trachomatis* are limited to one small study in which a single oral dose of 20 mg/kg per day for 3 days appeared effective.³⁷⁰

Although the safety and efficacy of azithromycin and clarithromycin have not been determined for infants younger than 6 months of age (or for pregnant or lactating women), these antimicrobials are recommended as first-line agents for treatment and postexposure prophylaxis of pertussis in individuals older than the age of 1 month, based on their in vitro effectiveness, safety and efficacy in older children, and more convenient dosing schedule. Duration of therapy or prophylaxis for pertussis is 14 days for erythromycin (40 to 50 mg/kg per day in four divided doses), 7 days for clarithromycin (15 mg/kg per day in two divided doses), and 5 days for azithromycin (10 mg/kg as single daily doses for infants <6 months of age; 10 mg/kg as a single dose on day 1, then 5 mg/kg per day on days 2 to 5 for infants and children ≥6 months of age). Azithromycin is the preferred macrolide for postexposure prophylaxis and treatment of pertussis in neonates because it has fewer adverse effects in contrast to erythromycin.³⁵⁰ Infants younger than 6 weeks of age treated with either oral erythromycin or azithromycin should be closely monitored because there is an association between receipt of these oral agents and the development of infantile hypertrophic pyloric stenosis.¹⁰⁷ A multicenter study established that children with cystic fibrosis chronically infected with *P. aeruginosa* had significantly improved lung function and clinical endpoints associated with

azithromycin treatment three times per week.³¹¹ This effect may not persist. Studies in endemic regions showed that a single dose of azithromycin is as effective as standard therapy with erythromycin for treatment of cholera in children.¹⁹⁰ A 5-day course of azithromycin (20 mg/kg per day; maximum dose, 1 g) is an effective treatment for uncomplicated typhoid fever in children and adolescents.¹²⁴ One to six doses of azithromycin for trachoma have been shown to be equivalent to prolonged topical treatment with oxytetracycline polymyxin ointment.⁹⁷

Adverse Effects

The macrolides usually are well tolerated and relatively safe. The most common adverse effect is gastrointestinal disturbance, which can occur with the administration of any macrolide but is associated most commonly with the use of erythromycin. It is a dose-related phenomenon. Because it acts as a motilin receptor agonist, gastrointestinal symptoms (i.e., nausea, vomiting, diarrhea, flatulence, and abdominal cramps) can occur with orally or parenterally administered erythromycin. Enteric coating of erythromycin does not decrease the incidence. Rapid intravenous infusions of erythromycin can result in thrombophlebitis. Cholestatic hepatitis is an unusual, but serious, macrolide toxicity. It occurs more commonly in adults and possibly in pregnant women and is associated most frequently with the estolate preparation.⁵⁷ The onset typically begins approximately 16 days after initiation of therapy and is manifested as fever, pruritus, jaundice, elevated liver function tests, and, occasionally, rash, leukocytosis, and eosinophilia. Signs and symptoms resolve after discontinuation of the macrolide but recur with subsequent therapy. Transient hearing loss has been described after the administration of large dosages of erythromycin lactobionate. Torsades de pointes is an uncommon reaction to intravenous infusions of erythromycin. A sevenfold increase in the rate of infantile hypertrophic pyloric stenosis was temporally associated with and probably causally related to the prophylactic use of erythromycin in neonates during a pertussis outbreak in a community hospital.¹⁵⁶ Azithromycin exposure in the first 2 weeks of life was associated with an eightfold increased risk of developing pyloric stenosis in a retrospective review using the US military health system database.¹⁰⁷ Postmarketing experience with the use of intravenous azithromycin reported two cases of infantile pyloric stenosis. Gastrointestinal disturbances occur less frequently with clarithromycin and azithromycin, principally because lower dosages are required for effective therapy.

A common and potentially serious toxicity is that of drug interactions.²⁷¹ Macrolides are metabolized by hepatic microsomal CYP450 enzymes. Drug interactions can occur during concomitant therapy with two or more drugs that undergo hepatic microsomal P450 metabolism. One proposal for this drug interaction suggests that the macrolide is N-demethylated to a nitrosoalkane that interacts with and inactivates the microsomal enzyme. Toxicity can occur because of interference with metabolism and consequent accumulation of the second drug. The ability to inactivate the enzyme varies with each macrolide; erythromycin is a more potent inhibitor than is clarithromycin. Azithromycin has not yet been associated with nitrosoalkane formation and resulting drug interactions, but caution should be exercised with concomitant administration of warfarin, digitoxin, and antacids. Drugs with which macrolides can interact include astemizole, benzodiazepines, buspirone, carbamazepine, cimetidine, cisapride, cyclosporine, digoxin, methylprednisolone, rifampin, tacrolimus, terfenadine, theophylline, triazolam, verapamil, warfarin, zidovudine, and certain protease inhibitors, among others.²⁷¹

Chloramphenicol

Chloramphenicol, originally derived from *Streptomyces venezuelae* obtained from soil near Caracas, Venezuela, in 1947, now is prepared synthetically. It is a chemically unique agent that contains an aromatic nitro group, an N-dichloroacetyl substituent, and two chiral centers. The availability of less toxic and equally or more effective agents has limited the usefulness of chloramphenicol in the United States.

Mechanisms of Action

Chloramphenicol reversibly binds to the 50S subunit of 70S bacterial ribosomes and thereby inhibits protein synthesis. The mechanism of

action involves suppression of peptidyltransferase activity, with a resultant inability to form peptide bonds and elongate the peptide chain.^{319,372} Because the ribosomal binding sites of chloramphenicol overlap with those of macrolides, clindamycin, and linezolid, concomitant use of these antibiotics can result in antagonism and should be avoided. Chloramphenicol usually is bacteriostatic, but it can be bactericidal when high concentrations are achieved against highly susceptible organisms such as meningococci and *H. influenzae*.

Mechanisms of Resistance

The most common mechanism of acquired resistance is plasmid-mediated production of chloramphenicol acetyltransferases (CATs), which acetylate chloramphenicol and render it unable to bind to the ribosomal target. Numerous CAT genes encode classic (type A) or novel (type B) CATs and may be associated with multidrug resistance phenotypes. This resistance has been documented in many different genera of bacteria, including *H. influenzae*, members of the Enterobacteriaceae, *Neisseria*, streptococci, and *S. aureus*. Less commonly, multiple specific or multidrug transporter mechanisms (efflux pumps) and chromosomal or plasmid-mediated alterations in permeability have resulted in chloramphenicol resistance in a wide range of bacteria, including *B. cepacia*, *E. coli*, *H. influenzae*, *P. aeruginosa*, and *S. typhi* (in the absence of OmpF protein). More recently described alterations in bacterial 23S rRNA have been associated with chloramphenicol resistance by inducing frameshift mutations and readthrough of stop codons.³⁴⁸ In addition, isolated cases of resistance in *Bacillus subtilis* because of altered ribosomes and in anaerobes because of inactivation of chloramphenicol by nitroreduction have been reported.³¹⁹

In Vitro Activity

Chloramphenicol has broad-spectrum activity against aerobic and anaerobic gram-positive and gram-negative bacteria, chlamydiae, mycoplasmas, spirochetes, and rickettsiae.²⁹⁵ It is bactericidal against susceptible strains of *H. influenzae*, *N. meningitidis*, and penicillin-susceptible *S. pneumoniae*, whereas it is bacteriostatic against most other susceptible microorganisms.²⁸⁸ Frequently susceptible aerobic gram-positive cocci include groups A and B β -hemolytic streptococci, viridans streptococci, and penicillin-susceptible pneumococci. Because penicillin-resistant pneumococci may be tolerant to chloramphenicol in vitro, meaning that concentrations of drug necessary to kill these pneumococci are approximately 30-fold higher than necessary to inhibit the organism, verifying chloramphenicol susceptibility by MBC testing is prudent, especially when treating meningitis.¹²⁵ Usually, chloramphenicol is active against oxacillin-susceptible *S. aureus*, but susceptibility patterns vary with the use of chloramphenicol, and more suitable alternatives for therapy exist. Susceptible gram-positive bacilli include *Bacillus* spp., *L. monocytogenes*, *C. diphtheriae*, *Clostridium* spp., and *Eubacterium*. Most *N. meningitidis* and *N. gonorrhoeae* organisms are susceptible.¹⁷⁹ However, several high-level chloramphenicol-resistant strains of meningococcus belonging to serogroup B were isolated from the CSF of children in Vietnam.¹²⁶ The susceptibility of Enterobacteriaceae, including for *Salmonella* and *Shigella* spp., is variable. Other gram-negative bacilli frequently susceptible to chloramphenicol include *B. pertussis*, *B. cepacia*, *Brucella* spp., *C. jejuni*, *F. tularensis*, *H. influenzae*, *Pasteurella multocida*, *Pseudomonas pseudomallei*, *V. cholerae*, and *Y. pestis*. Virtually all obligate anaerobes are susceptible.

Pharmacokinetics

After oral administration, absorption of chloramphenicol is rapid and complete. Bioavailability is approximately 80% after oral administration, but it is only 70% after an intravenous dose because approximately 30% of the parenterally administered dose is excreted in urine before hydrolysis of the succinate ester to the active form. Intramuscular injection results in peak serum concentrations comparable to those achieved after intravenous infusion. Because of its lipid solubility, chloramphenicol diffuses rapidly and widely into tissues and fluids.²⁹⁵ The highest concentrations are achieved in the liver and kidneys, with high concentrations present in urine, and therapeutic concentrations are achieved in aqueous and vitreous humor. CSF concentrations range from 21% to 50% and from 45% to 89% of serum values in the presence

of uninflamed and inflamed meninges, respectively. Brain tissue concentrations exceed those in plasma. Chloramphenicol also is distributed into pleural, ascitic, and synovial fluids, as well as saliva and breast milk. Protein binding ranges from 32% in premature newborns to 50% to 60% in adults. Chloramphenicol palmitate and chloramphenicol sodium succinate are esterified prodrugs of chloramphenicol. Orally administered chloramphenicol palmitate is hydrolyzed to active drug by pancreatic esterases in the small intestine before absorption. After intravenous infusion, chloramphenicol sodium succinate is hydrolyzed rapidly to active drug in the kidneys, liver, and lungs. Ninety percent of active chloramphenicol is conjugated to the inactive glucuronide primarily by the liver. Immature metabolic function of the liver in the fetus and newborn results in inadequate conjugation of chloramphenicol, with subsequent accumulation of toxic concentrations of active drug. Peak serum concentrations in children after a dose of 25 mg/kg range from 19 to 28 $\mu\text{g/mL}$, whereas in adults receiving doses of 12.5 mg/kg, peak serum values of 11 to 18 $\mu\text{g/mL}$ can be achieved. Although metabolized to inactive metabolites by the liver, chloramphenicol is excreted by the kidneys: 5% to 10% as active drug and 80% as inactive metabolites. The elimination half-life is significantly longer but variable, and serum concentrations are unpredictable in neonates.²⁹⁵ Dosage adjustments should be considered in persons with severe hepatic insufficiency or combined hepatic and renal insufficiency and in patients receiving drugs that compete for hepatic CYP450 oxidases, such as phenytoin, phenobarbital, and rifampin. Chloramphenicol is not removed by peritoneal dialysis or hemodialysis, but charcoal hemoperfusion may lower serum concentrations.

Indications for Use

Because of its low therapeutic-toxic index, use of chloramphenicol should be reserved for serious infections for which less toxic agents are ineffective or contraindicated. In developed countries, chloramphenicol has been replaced by third-generation cephalosporins for the treatment of bacterial meningitis and by clindamycin or metronidazole for the treatment of anaerobic infections. Ceftriaxone is a safe and effective alternative to (1) chloramphenicol for the treatment of acute typhoid fever²⁴⁶ and (2) long-acting oily chloramphenicol for epidemic meningococcal meningitis in sub-Saharan Africa.²⁵⁸ Infections for which chloramphenicol may be indicated include pneumococcal, meningococcal, and *H. influenzae* meningitis in β -lactam-allergic individuals; brain abscesses caused by susceptible anaerobic bacteria resistant to other agents; acute typhoid fever; and rickettsial infections (i.e., typhus, Q fever, Rocky Mountain spotted fever). Doxycycline is preferred for treatment of rickettsial infections in children, even those younger than 9 years of age. Chloramphenicol is not indicated for the treatment of trivial infections, prophylaxis of infections, or treatment of typhoid carrier states.

Adverse Effects

Hematologic adverse events associated with the use of chloramphenicol include hemolytic anemia in patients with the Mediterranean type of glucose-6-phosphate dehydrogenase deficiency, reversible bone marrow suppression, and aplastic anemia. Reversible bone marrow suppression is a dose-related phenomenon. It usually occurs when serum concentrations exceed 25 $\mu\text{g/mL}$, as can be seen when administering large dosages, during prolonged therapy, or in patients with impaired liver function. Although mammalian cells contain 80S ribosomes, rather than the 70S ribosomes found in prokaryotes, mitochondria possess 70S ribosomes. A proposed mechanism of myelosuppression involves inhibition of mitochondrial protein synthesis in host bone marrow stem cells.³¹⁹ Dose-related bone marrow suppression is manifested by peripheral anemia with or without reticulocytopenia, leukopenia, and thrombocytopenia and bone marrow findings of increased cellularity, cytoplasmic vacuolization, and maturation arrest of erythroid and myeloid precursors. In contrast, aplastic anemia is a rare, often fatal idiosyncratic reaction that is unrelated to the dosage, duration, or route of therapy. The pathogenesis is understood less well but possibly is related to DNA damage from toxic metabolites of chloramphenicol produced by nitroreduction.³⁷² The incidence ranges from 1 per 25,000 to 1 per 40,000 courses. Onset can begin during therapy but typically occurs

weeks to months or, rarely, years after therapy has been discontinued. Manifestations include peripheral pancytopenia and hypoplastic or aplastic marrow.

Gray syndrome, or gray baby syndrome, is a rare but serious and potentially fatal adverse event that usually occurs in newborn and young infants, but has been described in older children and adults with hepatic insufficiency. Most often, this syndrome occurs when serum chloramphenicol concentrations exceed 40 µg/mL and is thought to be a result of inhibition of mitochondrial electron transport in liver, skeletal muscle, and myocardium. The onset typically begins 2 to 9 days after initiating therapy. Manifestations include hypothermia, tachypnea, blue-gray skin color (cyanosis), abdominal distention, emesis, unresponsiveness, and refractory metabolic acidosis that can progress to vasomotor collapse and death within 2 days.

Uncommon side effects include hypersensitivity reactions such as drug fever, rash, urticaria, anaphylaxis, and a Herxheimer-like reaction during therapy for syphilis, typhoid fever, and brucellosis; gastrointestinal symptoms, including nausea, emesis, diarrhea, and an unpleasant taste; and neurologic symptoms such as peripheral neuritis, headache, mental confusion, and optic neuritis, the last of which may not be entirely reversible.

Chloramphenicol can inhibit the metabolism of other drugs metabolized by the hepatic microsomal CYP450 system and thus result in the accumulation of alfentanil, barbiturates, cyclophosphamide, phenytoin, antidiabetic sulfonylureas (more common with chlorpropamide and tolbutamide than with glyburide and glipizide), and warfarin during concomitant therapy.⁷ Because some agents such as rifampin, phenobarbital, and phenytoin are potent inducers of hepatic microsomal enzymes, when they are given concomitantly with chloramphenicol, metabolism is enhanced, and serum concentrations of active chloramphenicol are reduced. Other drug interactions include a reduction in the effectiveness of estrogen-containing oral contraceptives when used concurrently with chloramphenicol and a delay in the response to vitamin B₁₂, folic acid, and iron. A mild disulfiram-like reaction can occur when alcohol is ingested during chloramphenicol therapy. Both cimetidine and chloramphenicol have rare associations with aplastic anemia; a few reports of concomitant use resulting in aplastic anemia have been documented, thus suggesting a potential for additive or synergistic risk. Concomitant acetaminophen therapy has been the subject of controversy; some studies suggest that coadministration can prolong the elimination half-life of chloramphenicol, but other reports suggest no effect or enhanced metabolism of chloramphenicol. Lincosamides and macrolides can have an antagonistic effect when they are administered concurrently with chloramphenicol because of competition for ribosomal binding sites. Chloramphenicol is physically incompatible in solution with many drugs, including tetracyclines and vancomycin.

Because of considerable variability in serum chloramphenicol concentrations, the narrow therapeutic-toxic index, and the potential for drug interactions, monitoring serum concentrations of chloramphenicol and peripheral blood counts during therapy is prudent, particularly for neonates.

Tetracyclines

Chlortetracycline (Aureomycin) was the first natural tetracycline discovered when isolated from *Streptomyces aureofaciens* in 1948.¹¹⁶ Many tetracyclines have been developed since then. Those currently marketed include the natural agents tetracycline and demeclocycline and the semisynthetic agents doxycycline and minocycline. Their basic structure consists of a hydronaphthacene nucleus with four fused rings. They differ from each other biochemically by substituent variations at carbons 5, 6, or 7. Their mechanisms of action and mechanisms of resistance, as well as their spectra of activity, are similar, but the analogues differ in the degree of activity and pharmacokinetic properties. Tigecycline is a novel intravenously administered glycylcycline that is related structurally to minocycline. It is approved for use in adults with complicated skin and skin structure infections, community-acquired pneumonia, and complicated intra-abdominal infections. It is bacteriostatic, with improved activity against multidrug-resistant bacteria, and it has no cross resistance with other classes of antimicrobial agents. Tigecycline has activity against *S. aureus* (including MRSA), enterococci

(including VRE), and multidrug-resistant gram-negative bacteria, including ESBL-producing enteric gram-negative organisms. It is also active against rapidly growing, nontuberculous mycobacteria. It is not recommended for serious infections caused by *P. aeruginosa*.²⁶⁶

Mechanisms of Action

Tetracyclines passively diffuse through outer-membrane porins and then traverse the cytoplasmic membrane by energy-dependent active transport. Tetracyclines are actively concentrated by most bacterial cells, but not by mammalian cells, a characteristic that explains the selective action of these drugs against bacteria. Tetracyclines are bacteriostatic agents that reversibly bind to the 30S subunit of 70S bacterial ribosomes and inhibit protein synthesis. Because attachment of aminoacyl-tRNA to the ribosome acceptor site is prevented, the bacteria are unable to add amino acids to the growing peptide chain.

Mechanisms of Resistance

In many bacteria, including members of the Enterobacteriaceae, *P. aeruginosa*, staphylococci, streptococci, and *Bacteroides*, resistance to tetracyclines has developed. Resistance in most bacteria results from the acquisition of new genes often associated with mobile elements such as plasmids or transposons, but it also can be chromosomally mediated. The genes encoding for acquired resistance are called tet (tetracycline)-resistance or otr (oxytetracycline)-resistance determinants. Resistance to one tetracycline usually implies resistance to all; however, many tetracycline-resistant bacteria are susceptible to doxycycline, minocycline, or both. At least 38 acquired tetracycline and oxytetracycline resistance genes have been identified that mediate (1) energy-dependent efflux of tetracycline (the most common type of resistance mechanism), (2) protection of the ribosomes from the action of tetracycline, or (3) enzymatic inactivation of tetracycline.²⁹⁷ Tet genes that encode membrane efflux proteins are different in gram-positive and gram-negative bacteria. Efflux has been found in a wide range of bacteria, including *Acinetobacter*, *Aeromonas*, *Chlamydia*, the Enterobacteriaceae, *Haemophilus*, *Moraxella*, *Neisseria*, *Pseudomonas*, staphylococci, *Stenotrophomonas*, *V. cholerae*, and others. Less commonly, ribosomal protection by a soluble ribosomal protection protein encoded by different tet and otr genes has been found in a wide variety of aerobic and anaerobic gram-positive and gram-negative bacteria. The precise mechanism by which ribosomal protection protein mediates resistance to tetracyclines is being investigated. Researchers have hypothesized that these protection determinants produce allosteric disruption of the primary tetracycline binding site that causes the tetracycline molecules to be released from the ribosome. Enzymatic inactivation of tetracycline, encoded for by other tet genes, has been demonstrated in *in vitro* studies of *Bacteroides*, and *E. coli*, but the clinical significance has not been established.²⁹⁷ Susceptibility of staphylococci to this class of agents typically is tested using tetracycline. However, this approach may overestimate the prevalence of resistance to doxycycline and minocycline. Although the prevalence of tetracycline resistance remains relatively low among CAMRSA isolates, resistance in some strains has been associated with tetK, a finding indicating that doxycycline and minocycline may be effective treatment options. However, because data are sparse on clinical outcomes associated with the use of minocycline or doxycycline to treat infections caused by tetracycline-resistant *S. aureus* strains, these agents are not recommended.¹³⁶ Tigecycline overcomes two major resistance mechanisms, including drug efflux and protection of ribosomes.

In Vitro Activity

Tetracyclines are broad-spectrum antibiotics with activity against aerobic and anaerobic gram-positive and gram-negative bacteria, chlamydiae, mycoplasmas, rickettsiae, and spirochetes. Activity against gram-negative bacteria has been limited by the emergence of tetracycline-resistant strains. Most *P. aeruginosa* and many *Shigella* and *Salmonella* organisms are resistant. Penicillin-susceptible strains of *N. gonorrhoeae* and *N. meningitidis* usually are susceptible to tetracyclines, but penicillin-resistant strains of *N. gonorrhoeae* are not. Gram-negative organisms with continued susceptibility to tetracyclines include *Aeromonas hydrophila*, *Brucella*, *Campylobacter*, some *Haemophilus* organisms, *Helicobacter*, *P. multocida*, *Plesiomonas shigelloides*, and *Vibrio*. Tetracyclines are active

against some gram-positive bacilli, including *A. israelii*, *B. anthracis*, many clostridia, *Listeria*, and *Nocardia*. Tetracyclines have excellent activity against *C. pneumoniae*, *M. pneumoniae*, and rickettsiae. Other organisms for which tetracyclines have activity include *Mycobacterium marinum* and *Borrelia burgdorferi*. The more lipophilic agents doxycycline and minocycline generally are more active than the others. Minocycline has excellent activity against susceptible staphylococci, and both doxycycline and minocycline are more active than tetracycline against *S. aureus* and some streptococci, but they have no activity against enterococci and group B streptococci. Because of extensive plasmid-mediated resistance in pneumococci, therapy with tetracycline should be avoided. Doxycycline and minocycline are more active in vitro than the other agents against anaerobic bacteria, but alternative antimicrobials are preferred for anaerobic infections because more than 50% of *B. fragilis* isolates are resistant, and susceptibility among other anaerobes is highly variable.²⁹⁶

Pharmacokinetics

The four tetracycline compounds available for systemic use can be classified by duration of activity: tetracycline is a short-acting agent, demeclocycline is intermediate acting, and doxycycline and minocycline are long-acting agents. Oral administration is the preferred route because thrombophlebitis is associated with intravenous infusion and pain is associated with intramuscular injections. Oral absorption ranges from 58% for the short-acting agents to 100% for the long-acting ones. The presence of food decreases the absorption of demeclocycline and tetracycline. Because tetracyclines form insoluble complexes in the gut with aluminum, calcium, iron, magnesium, zinc, and other bivalent and trivalent cations, coadministration with milk and other dairy products, antacids, calcium or iron supplements, cathartics, and other agents can reduce absorption and should be avoided. Differences in lipid solubility affect penetration of tissues by the various tetracyclines. All agents readily penetrate many tissues and fluids, among which are pleural, ascitic, and synovial fluids, sinus secretions, sputum, bone, teeth, and breast milk. Tetracyclines can cross the placenta. The highest concentrations are achieved in bile and can exceed serum concentrations by 5 to 20 times. Therapeutic concentrations of doxycycline can be achieved in tonsillar and pulmonary tissues, the eye, and the prostate, and high concentrations are achieved in myometrial and endometrial tissue and the kidney.³¹² Minocycline penetrates into sputum, saliva, and tears, as well as into cells of the vestibular apparatus.¹⁷⁴ Minocycline is biotransformed to inactive metabolites by the liver; the other tetracyclines are not metabolized, although whether doxycycline is metabolized is not clear. Demeclocycline and tetracycline are eliminated unchanged in urine. Approximately 10% of minocycline is excreted unchanged in urine, 20% to 35% is excreted unchanged in feces, and the remainder is excreted as inactive metabolites in urine and feces. Thirty percent to 40% of doxycycline is excreted in urine; the remainder is excreted by the biliary tract and by diffusion through the intestinal wall, where some of it is chelated and prevented from reabsorption and enterohepatic cycling. Dosing of short- and intermediate-acting tetracyclines must be adjusted for renal failure.

Systemic formulations available in the United States include tablets, capsules, delayed-release capsules, and suspensions for many of the tetracyclines, as well as parenteral preparations of doxycycline and minocycline. Ophthalmic and topical preparations also are available. Tigecycline is available only as a parenteral formulation.

Indications for Use

With few exceptions, tetracyclines no longer are the drugs of choice for many infections because of the availability of cephalosporins and semisynthetic penicillins with equivalent or greater activity and less frequent side effects. As a result of the potential for dental toxicity, tetracyclines are not recommended for use in children younger than 8 years of age, except for specific infections for which alternative therapy is potentially more toxic, such as chloramphenicol for Rocky Mountain spotted fever and ehrlichiosis.² Approved indications in the United States include treatment of actinomycosis, anthrax, brucellosis, inclusion conjunctivitis, psittacosis, Q fever, rickettsialpox, Rocky Mountain spotted fever, typhus, relapsing fever, syphilis, trachoma, yaws, and Vincent

necrotizing gingivostomatitis caused by *Fusobacterium*, as well as infections caused by *Bacteroides* spp., *Bartonella bacilliformis*, *Campylobacter fetus*, *F. tularensis*, *M. pneumoniae*, *V. cholerae*, *Y. pestis*, and others. Because of its excellent tissue penetration and spectrum of activity, doxycycline is the preferred tetracycline for treatment of atypical pneumonia caused by *M. pneumoniae* and *C. pneumoniae*, intra-abdominal or pelvic infections, and several STDs, including granuloma inguinale, chlamydial infections, *U. urealyticum* infection, nongonococcal urethritis, pelvic inflammatory disease (plus cefotetan or cefoxitin, ampicillin-sulbactam or single-dose ceftriaxone with or without metronidazole), acute epididymitis (plus ceftriaxone), proctitis (plus ceftriaxone), and prostatitis.³⁷⁰ Doxycycline is an alternative drug for (nonpregnant) penicillin-allergic patients with primary, secondary, or late latent syphilis. Although minocycline is effective in eradicating nasopharyngeal carriage of meningococcus, its potential for vestibular toxicity precludes its use for this purpose. For prevention of Lyme disease after a recognized tick bite, a single dose of doxycycline may be offered to adults (200 mg dose) and to children older than 8 years of age (4 mg/kg, up to a maximum dose of 200 mg), provided the following criteria are met: (1) the attached tick can be identified reliably as an adult or nymphal *Ixodes scapularis* tick that is estimated to have been attached for more than 36 hours on the basis of the degree of engorgement of the tick, (2) prophylaxis can be started within 72 hours of tick removal, and (3) the local rate of infection of these ticks with *B. burgdorferi* is more than 20%. Doxycycline (4 mg/kg per day in two divided doses, up to 100 mg per dose) is indicated in children older than 8 years of age and adults for treatment of erythema migrans, isolated cranial nerve palsy, uncomplicated cardiac disease, and uncomplicated arthritis.³⁷¹ Topical tetracyclines have been used extensively for the treatment of acne vulgaris and other dermatologic illnesses.¹⁶⁰

Adverse Effects

Gastrointestinal disturbances are the most common side effects associated with tetracycline and include anorexia, nausea, emesis, flatulence, and diarrhea. These symptoms occur less frequently with minocycline. Esophageal ulceration has been associated with the oral administration of tetracyclines.¹¹⁹ All tetracyclines except doxycycline can cause a negative nitrogen balance, with an elevation in blood urea nitrogen that usually is not significant except in the presence of underlying renal insufficiency. Demeclocycline can cause nephrogenic diabetes insipidus and, for this reason, has been used for treatment of the syndrome of inappropriate antidiuretic hormone secretion. Rarely, tetracyclines have been associated with hepatic injury, as manifested by elevated transaminases and diffuse vacuolar fatty metamorphosis on biopsy, with or without pancreatitis. The effect is dose related, and the risk is increased with pregnancy, malnutrition, and preexisting renal or hepatic disease and in patients receiving other hepatotoxic agents. The use of tetracyclines in children younger than 8 years of age is relatively contraindicated because tetracyclines chelate with calcium and can be deposited in developing bones and teeth and lead to a transient decrease in bone growth, permanent tooth discoloration, and enamel hypoplasia. The risk that these side effects will occur with one course at an appropriate dosage is low; the degree of tooth discoloration is associated with the total dosage administered.¹⁴⁰ Minocycline has been associated with reversible vestibular toxicity. All tetracyclines have been noted to cause pseudotumor cerebri, a benign elevation in intracranial pressure that is reversible after discontinuation of the drug. Some data suggest that an increased risk may exist with the concurrent use of tetracycline and isotretinoin. Tetracyclines have been associated with an exaggerated sunburn reaction after sun exposure. This risk occurs most frequently with demeclocycline and rarely with minocycline. Hypersensitivity reactions occur infrequently and include morbilliform rash, urticaria, exfoliative dermatitis, and, rarely, anaphylaxis. Hyperpigmentation of the mucosal membranes, skin, and nails has been reported with the use of tetracycline, particularly minocycline.

Drug-drug interactions are numerous. A decrease in absorption of tetracyclines can occur with the coadministration of oral antacids, bismuth subsalicylate, iron, kaolin or pectin, zinc sulfate, and other divalent or trivalent cations that chelate the antibiotic. A reduced effect of tetracyclines because of increased metabolism is associated with the

concomitant use of doxycycline with barbiturates, carbamazepine, phenytoin, rifampin, and alcohol in heavy drinkers. Coadministration with tetracyclines can increase the effect of oral anticoagulants, digoxin, lithium, and theophylline and can decrease the effect of oral contraceptive agents and oral iron. Tetracyclines can inhibit the in vitro bactericidal activity of penicillins and aminoglycosides. Other drug-drug interactions include benign intracranial hypertension with the concomitant administration of vitamin A, severe nephrotoxicity with the coadministration of methoxyflurane and tetracycline, and localized hemosiderosis with amitrityline and minocycline.

Lincosamides

Lincosamide antibiotics consist of an amino acid linked to an amino sugar. Lincomycin, elaborated by *Streptomyces lincolnensis* var. *lincolnensis*, originally isolated from a soil sample near Lincoln, Nebraska, was the first lincosamide available for use. Clindamycin, a semisynthetic derivative of lincomycin produced by the substitution of a chlorine atom for a hydroxyl group at position 7, was available for use in the early 1970s. Because clindamycin has increased antibacterial activity and better oral absorption than lincomycin, lincomycin rarely is used.

Mechanisms of Action

Lincosamides bind to the 50S subunit of susceptible bacterial ribosomes close to the peptidyl transferase center and thereby inhibit protein synthesis. Data indicate that clindamycin causes dissociation of peptidyl-tRNAs from the ribosome, depletion of free tRNA pools, and prevention of the egress of nascent peptides through a tunnel in the 50S subunit.³⁴⁴ Because the ribosomal binding sites for lincosamides overlap with those of chloramphenicol and erythromycin, concurrent use of these agents can result in antagonism and should be avoided. Lincosamides usually are bacteriostatic but can be bactericidal against highly susceptible microorganisms in the presence of high lincosamide concentrations.

Mechanisms of Resistance

Some bacteria, including members of the Enterobacteriaceae and *Pseudomonas* and *Acinetobacter* spp., are inherently resistant to lincosamides, most likely because of relative impermeability of the outer membrane of the cell wall. Acquired resistance can develop as a result of altered ribosomal targets and, less commonly, lincosamide inactivation, whereas resistance as a result of reduced lincosamide uptake has not been described. Two mechanisms by which bacteria can alter their ribosomes and acquire lincosamide resistance have been identified. High-level resistance because of an altered protein component of the 50S ribosomal subunit after a one-step chromosomal mutation confers resistance to erythromycin and often to the lincosamides. Plasmid-mediated MLS_B resistance occurs when adenine residues on the 23S RNA component of the 50S ribosomal subunit are methylated, and an altered target is created that confers cross resistance to macrolides, lincosamides, and streptogramin B. The production of ribosomal methylases is encoded by the *erm* class of genes.²⁹⁹ This resistance can be constitutive or inducible and can be seen in staphylococci, streptococci, and *Bacteroides* spp. Erythromycin is the most potent inducer of MLS_B resistance in staphylococci, whereas any macrolide, lincosamide, or streptogramin B can be an inducer in streptococci. Some strains of *B. fragilis* can have inducible MLS_B resistance that is not detected easily by disk agar diffusion susceptibility testing³³⁷ but is recognizable because of frequently concurrent high-level erythromycin resistance. A macrolide-spectrogramin-B pattern of resistance that is plasmid mediated results in macrolide resistance as a result of active ATP-dependent efflux pumps encoded by the *mef(A)* and *msr(A)* genes. Isolates with these resistance genotypes are resistant to 14- and 15-membered ring macrolides and streptogramin B but not to clindamycin.²³¹ Rarely, staphylococci produce a plasmid-mediated, nonconjugative nucleotidyltransferase that inactivates lincosamides and results in high-level resistance to lincomycin and tolerance to clindamycin (MBC/MIC ratio >32).

In Vitro Activity

Both lincosamides are effective in vitro against gram-positive cocci, whereas clindamycin also is active against a wide range of anaerobic bacteria. Clindamycin is many times more active than lincomycin and

is as active as or slightly more active than erythromycin against staphylococci, pneumococci, group A streptococci, and viridans streptococci. Unlike erythromycin, the lincosamides do not have clinically significant activity against *H. influenzae*, *M. pneumoniae*, or *Neisseria* spp. Clindamycin is active against many gram-positive cocci, including penicillinase-producing and non-penicillinase-producing staphylococci and groups A, B, C, and G β -hemolytic streptococci and pneumococci, but it is not active against enterococci or most health care-associated methicillin-resistant staphylococci. Rates of in vitro inducible erm-mediated MLS_B resistance among CAMRSA isolates vary widely, ranging from 4.5% in Houston¹⁸⁴ to 94% in Chicago.¹²¹ Presence of this type of resistance can be detected in erythromycin-resistant strains of *S. aureus* with the use of the double-disk diffusion assay (D-test), in which clindamycin- and erythromycin-impregnated disks are placed 15 to 20 mm apart on Mueller-Hinton agar that has been inoculated with a standardized (0.5 McFarland) suspension of *S. aureus*. The finding of a D-shaped blunting of the circular zone of inhibition around the clindamycin disk on the side closest to the erythromycin disk indicates the presence of in vitro-inducible MLS_B resistance. These isolates have a high rate of mutation to constitutive clindamycin resistance, a trait that would confer a selective advantage during clindamycin therapy. The use of clindamycin for D-test-positive *S. aureus* infections has been reported to result in treatment failure in a few patients. Therefore, alternative effective antimicrobial agents should be sought, or, if empirical clindamycin therapy has been initiated, response to therapy should be carefully monitored.^{136,231} Erythromycin and lincosamide resistance in pneumococci and group A streptococci has been increasing. Surveillance studies revealed rates of clindamycin resistance among multidrug-resistant pneumococci to be 12% and 19% in the United States and Europe, respectively.¹⁷³ Most facultative aerobic gram-negative bacilli, with the exception of *Campylobacter* spp. (including *C. jejuni* and *C. fetus*) and *H. pylori*, are inherently resistant to clindamycin. Anaerobes frequently susceptible to clindamycin include the anaerobic gram-negative bacilli *Bacteroides*, *Fusobacterium*, *Prevotella*, and *Porphyromonas* spp.; the non-spore-forming gram-positive bacilli *Propionibacterium*, *Eubacterium*, and *Actinomyces*; the anaerobic gram-positive cocci *Peptococcus*, *Peptostreptococcus*, and microaerophilic streptococci; and many *Clostridium* organisms, excluding *C. difficile*, *Clostridium sporogenes*, and *Clostridium tertium*. Clindamycin resistance does occur, especially in *Fusobacterium varium*, the non-fragilis *Bacteroides* group, an increasing proportion of *B. fragilis* isolates (about 30% or less in some series),⁵ and as many as 20% of anaerobic gram-positive cocci. When combined with other agents, clindamycin is active against certain other pathogens such as *Babesia*, *Plasmodium*, *Pneumocystis jiroveci*, and *T. gondii*.

Pharmacokinetics

Oral absorption of lincosamides occurs rapidly. The presence of food delays but does not decrease the absorption of clindamycin, but it does reduce the absorption of lincomycin. Concomitant administration of kaolin or attapulgite-containing antidiarrheal agents can decrease absorption; therefore, these agents should not be administered within 2 hours before or 3 to 4 hours after oral lincosamides are given. Lincosamides are distributed rapidly and widely to most tissues and fluids, including saliva, sputum, respiratory tissue, pleural fluid, soft tissues, bones and joints, brain, prostate, semen, appendix, and peritoneal fluid.^{257,272} Lincosamides are transported actively into macrophages and polymorphonuclear leukocytes, and high concentrations are achieved in bile, urine, and bone. Penetration into CSF is limited, unless inflammation is present. In experimental pneumococcal meningitis, concentrations of clindamycin in CSF were approximately 10% of the corresponding serum values. Lincosamides are highly protein bound, with values ranging from 70% to 75% for lincomycin and 92% to 94% for clindamycin. The inactive palmitate and phosphate esters are hydrolyzed in the liver to clindamycin, the active agent. Clindamycin undergoes hepatic biotransformation to active and inactive metabolites. Ten percent of absorbed lincomycin is excreted unchanged in urine, 3% is excreted unchanged in feces, and the remainder is excreted as inactive metabolites, primarily in the biliary system. Elimination is delayed in the presence of severe hepatic insufficiency alone or severe concurrent renal and hepatic

impairment, and therefore adjustments in dosages may need to be made. Formulations of lincosamides available for use include lincomycin hydrochloride solution for parenteral use. Clindamycin phosphate, a water-soluble ester of clindamycin and phosphoric acid, is available for parenteral use. Oral formulations include clindamycin palmitate hydrochloride granules reconstituted to 75 mg base/5 mL and clindamycin hydrochloride capsules containing 75, 150, and 300 mg of the base compound. Clindamycin also is available as a topical solution, gel, lotion, foam, pad, and vaginal cream and suppository.

Indications for Use

Lincomycin can be used for the treatment of serious infections caused by susceptible strains of staphylococci, pneumococci, other streptococci, or anaerobic organisms, but it rarely is used in pediatric patients. Clindamycin is effective against and has been approved for treatment of susceptible strains of staphylococcal bone and joint infections¹¹³; anaerobic pelvic infections, including pelvic inflammatory disease, nongonococcal tubo-ovarian abscess, and postsurgical vaginal cuff infections; anaerobic intra-abdominal infections, including peritonitis and abscesses; pneumonitis, empyema, and lung abscesses caused by anaerobes and as a second-line agent for infections caused by susceptible strains of pneumococci and staphylococci; anaerobic septicemia; and skin and soft tissue infections caused by anaerobes, susceptible strains of staphylococci, and streptococci. Clinical prediction rules relating to resistance among community-acquired, community-onset health care-associated and traditional nosocomial staphylococcal isolates are becoming less reliable because certain strains with distinctive genetic determinants of virulence (e.g., *pvl* genes) and antibiotic resistance (e.g., *SSCmec*) are tending to predominate.^{159,248} Prevalences of constitutive and inducible *MLS_B* resistance in community-associated *S. aureus* infections generally are increasing in the United States, although rates vary geographically and temporally as a function of predominant circulating clones.⁷⁶ Based on current experience, clindamycin should not be used for empirical therapy of suspected *S. aureus* infections if the local clindamycin resistance rate exceeds 10% to 15%. Conversely, clindamycin is effective in treating serious infections caused by clindamycin-susceptible (D-test-negative) CAMRSA infections, including bacteremia, osteomyelitis, suppurative arthritis, pleural empyema, and skin and soft tissue infections.^{182,231} Clindamycin also is effective and has been approved as a topical agent for acne vulgaris. Unconfirmed retrospective data suggest that clindamycin in combination with a β -lactam antibiotic, with surgery if indicated, may be the most effective treatment of invasive *S. pyogenes* infections.³⁸² Other infections for which clindamycin may be effective but has not been approved for therapy include acute otitis media caused by penicillin-resistant pneumococci that has failed to respond to other antibacterial agents,¹¹ chronic suppurative otitis media or chronic sinusitis in which anaerobes may play a role, chronic pharyngeal carriers of group A streptococci,³³⁸ odontogenic infections, toxoplasmosis of the CNS (in combination with pyrimethamine), uncomplicated *falciparum* malaria²⁰⁰ or babesiosis (in combination with quinine), and mild-to-moderate *P. jiroveci* pneumonia in patients with acquired immunodeficiency syndrome (AIDS) (in combination with primaquine).³⁵ Because of poor penetration into CSF, this drug is not approved for the treatment of meningitis. Clindamycin is a third-line agent for endocarditis prophylaxis for upper respiratory tract, dental, or oral procedures in persons allergic to or intolerant of amoxicillin and erythromycin. Oral and intravenous formulations of clindamycin are approved for use in infants and children of all ages. The bitter taste of the oral suspension may limit compliance.

Adverse Effects

The most frequent side effects include generalized morbilliform-like rash and mild, self-limited diarrhea occurring in as many as 10% and in 2% to 20% of patients, respectively. Other gastrointestinal disturbances include anorexia, nausea, vomiting, flatulence, abdominal pain, and a metallic taste. Pseudomembranous colitis, a serious and sometimes fatal illness, is the adverse event posing the most concern. Most antibiotics have been associated with pseudomembranous colitis, but those most frequently implicated include ampicillin, lincosamides, and cephalosporins. The incidence of lincosamide-associated pseudomembranous

colitis varies from 0.1% to 10%. Antibiotic-associated pseudomembranous colitis is caused by overgrowth of toxin-producing strains of *C. difficile*; at least two extracellular toxins are elaborated: toxin A, a potent enterotoxin; and toxin B, a cytotoxin.⁵⁸

Other less common adverse events include hypersensitivity reactions such as urticarial rash, drug fever, and eosinophilia; transient neutropenia, agranulocytosis, or thrombocytopenia; and a mild, reversible elevation in hepatic transaminases. Caution must be exercised when administering lincosamides to newborns; fatal gasping syndromes have been described that possibly are related to the preservative benzyl alcohol.

Drug interactions include incompatibility with many agents in solution, including ampicillin, barbiturates, calcium gluconate, phenytoin, and magnesium sulfate, as well as interaction with hydrocarbon-containing inhalational anesthetics. Lincosamides are weak neuromuscular blockers,³²⁶ but they can enhance neuromuscular blockade when they are administered concurrently with neuromuscular blockers. Chloramphenicol and macrolides can have an antagonistic effect when they are administered concurrently with lincosamides because of competition for ribosomal binding sites.

Linezolid

Linezolid is the first of a new class of oxazolidinone antibiotics that was approved for use in children by the FDA in 2002. Linezolid is a totally synthetic compound with favorable activity against multidrug-resistant, gram-positive bacteria.¹⁰²

Mechanisms of Action

Linezolid inhibits an early stage of ribosomal protein synthesis by binding to a unique site, domain V on the bacterial 23S ribosomal RNA of the 50S subunit, and prevents formation of a functional 70S initiation complex. Inhibition of this process interferes with the bacterial translation process. Furthermore, linezolid causes ribosomes to shift reading frames and to read through stop codons, thereby affecting translational fidelity.³⁴⁸

Mechanisms of Resistance

Rarely, mutations conferring resistance have been reported in the peptidyl transferase region of the 23S rRNA genes. Cross resistance between linezolid and chloramphenicol is caused by a single nucleotide mutation in the peptidyl transferase center.³⁴⁸ Cross resistance between linezolid and other classes of antibiotics that target the ribosome, such as aminoglycosides, macrolides, lincosamides, and streptogramins, rarely occurs because these agents target a distinct mechanism of protein elongation. Resistance to linezolid has been reported in enterococci, particularly *E. faecium*, *S. aureus*, and coagulase-negative staphylococci.¹⁰⁴ Predisposing factors include indwelling devices, undrained abscesses, and prolonged administration of linezolid, particularly if subtherapeutic antibiotic concentrations are achieved.²⁹⁸

In Vitro Activity

Time-kill studies demonstrated that linezolid is bacteriostatic against enterococci and staphylococci and bactericidal against most strains of streptococci. Linezolid is active against MRSA, coagulase-negative staphylococci, and vancomycin-resistant enterococci. Furthermore, linezolid has broad activity against *Nocardia* and rapidly growing mycobacteria, as well as slowly growing tuberculous and nontuberculous mycobacteria.⁵⁹

Pharmacokinetics

Dosage adjustment is not necessary when switching from intravenous to oral formulations because the oral bioavailability is approximately 100%. Absorption is not significantly affected by food. The antibiotic is distributed to well-perfused tissues and has a relatively low protein binding (31%) that contributes to the high degree of penetration into bone, muscle, fat, alveolar cells, lung extracellular lining fluid, and CSF. Linezolid is metabolized primarily by oxidation and has no interaction with the CYP450 enzymes. The elimination half-life in children is less than 5 hours and is shorter than in adults. The disposition of linezolid varies as a function of age, with faster clearance and greater volume of distribution in children less than 11 years of age. The AUC values for

children are lower than those for adults, whereas preterm neonates (gestational age <34 weeks) within the first week of life have larger AUC values than many full-term neonates and older children. The pharmacokinetics of linezolid in adolescents 12 years of age and older is not significantly different from that of adults. Dosage adjustment is not necessary for patients with renal insufficiency or mild-to-moderate hepatic insufficiency.¹⁸⁰

Indications for Use

The safety and effectiveness of linezolid have been established for pediatric patients from birth through 17 years of age. Intravenous and oral linezolid is indicated for treatment of children with (1) uncomplicated and complicated skin and skin structure infections caused by oxacillin-susceptible or oxacillin-resistant *S. aureus*, or by group A or group B β -hemolytic streptococci; (2) community- and health care-associated pneumonia caused by penicillin-susceptible strains of *S. pneumoniae* or oxacillin-susceptible or oxacillin-resistant *S. aureus*; and (3) infections caused by vancomycin-resistant enterococci.¹⁸³ The recommended dosage for newborns (≥ 34 weeks' postconceptional age) and children up to the age of 11 years is 10 mg/kg intravenously or orally every 8 hours for 10 to 14 days for pneumonia and complicated skin and skin structure infections and for 14 to 28 days for pneumonia or bacteremia caused by vancomycin-resistant enterococci. The 10-mg/kg dose is administered every 12 hours for 5- to 11-year-old children with uncomplicated skin and soft tissue infections and for premature neonates (gestational age <34 weeks) within the first week of life. The dose for adolescents older than 11 years and adults is 600 mg every 12 hours, with a 1200-mg daily limit. Linezolid offers a safe therapeutic alternative to vancomycin for multidrug-resistant, gram-positive bacteria and has the additional advantage of being available in an oral liquid preparation (100 mg/5 mL), which facilitates sequential intravenous and oral therapy.^{101,169,180,183} Safety and efficacy of therapy for longer than 28 days have not been evaluated in controlled clinical trials. Currently, no indication exists for treatment of mycobacterial infections, although linezolid has been used successfully for certain nontuberculous infections.

Adverse Effects

Data from multiple trials indicate that linezolid is safe and well tolerated, with adverse events similar to those of comparative drugs. The most common drug-related adverse events are diarrhea, nausea, vomiting, rash, and headache.³¹⁰ However, dose- and duration-dependent reversible myelosuppression, including mild-to-moderate anemia and thrombocytopenia and rarely neutropenia, have been reported in children treated with linezolid.^{239,310} Therefore, weekly monitoring of complete blood counts is recommended in patients who receive linezolid for longer than 2 weeks, have preexisting myelosuppression, or receive other myelosuppressive antibiotics. Other rare adverse effects that warrant prompt evaluation include peripheral and optic neuropathy, lactic acidosis, and the serotonin syndrome in patients receiving concomitant selective serotonin reuptake inhibitors. The oral suspension formulation contains phenylalanine, which is contraindicated in children with phenylketonuria.

Tedizolid

Tedizolid became the second commercially available compound to be added to the oxazolidinone drug class with FDA approval in 2014 for use in patients more than 18 years of age. Similar to the spectrum of activity of linezolid, tedizolid has activity against MRSA and VRE; however, tedizolid also has potent activity against staphylococcal and enterococcal multidrug-resistant isolates demonstrating linezolid resistance.^{304,380}

Mechanisms of Action

Similar to linezolid, tedizolid binding occurs at the 23S ribosomal RNA, called the V domain, of the 50S portion of the ribosome. This interaction prevents protein synthesis secondary to the inability to form a functional 70S initiation complex. The enhanced activity of tedizolid against linezolid-resistant strains occurs secondary to additional interactions between the side chain of tedizolid, also called the D-ring, and conserved areas of the ribosomal subunit.^{304,380}

Mechanisms of Resistance

Oxazolidinone resistance occurs via mutations or modifications of the ribosomal binding site secondary to (1) genetic mutation of 23S rRNA, (2) genetic mutation of ribosomal proteins L3 or L4, or (3) the presence of the *cfr* (i.e., chloramphenicol-florfenicol resistance) methyltransferase. The majority of linezolid-resistant isolates are a result of mutation to the 23S ribosomal subunit, where each additional mutation results in increased linezolid and tedizolid MICs for gram-positive organisms.^{304,309} The G2576T mutation is an important exception as only a single mutated copy results in increased oxazolidinone MICs. Oxazolidinone resistance has also been shown to occur via mutation to either the L3 or L4 ribosomal proteins, which results in two- to fourfold increases in linezolid MICs. When additional mutations are present with an L3 or L4 mutation, even larger MIC changes occur; however, tedizolid MICs are consistently four times lower than MIC elevations seen with linezolid.³⁰⁹ The *cfr* gene is horizontally transmissible because of its location on plasmids. The *cfr* gene confers resistance not only to linezolid but to additional antimicrobial agents including lincomycins, macrolides, aminoglycosides, fluoroquinolones, streptogramins, and amfenicols.³⁰⁴ Linezolid resistance due to the *cfr* gene mutation is thought to occur secondary to steric hindrance associated with its large side chain, but tedizolid has a compact side chain and its activity has not been shown to be impacted by *cfr* gene mutation alone.³⁸⁰ Overall, available surveillance data demonstrated 0.19% of 6884 gram-positive isolates with tedizolid MIC values greater than 1 μ g/mL.³⁰⁹

In Vitro Activity

Tedizolid demonstrates 4- to 16-fold greater potency when compared with linezolid against key gram-positive organisms such as staphylococci, streptococci, and enterococci where in vitro activity is bacteriostatic. Tedizolid is active against linezolid-resistant MRSA and VRE. In addition to its gram-positive activity, tedizolid also demonstrates twofold greater activity, when compared with linezolid, against select gram-negative organisms including *H. influenzae* and *M. catarrhalis*.^{218,283} In vitro tedizolid data demonstrate activity against *Nocardia brasiliensis* and *Mycobacterium tuberculosis*, even for *M. tuberculosis* isolates resistant to isoniazid and rifampin.²⁴⁵

Pharmacokinetics

Tedizolid phosphate is an inactive prodrug that undergoes rapid hydrolysis by serum phosphatases to the active compound, tedizolid.^{191,218} As a monophosphate ester, tedizolid phosphate demonstrates increased bioavailability, increased water solubility, and compound stability across a wide pH range.²¹⁸ Tedizolid exhibits near linear pharmacokinetics with increasing dosages demonstrating corresponding increases in AUC. The AUC of tedizolid phosphate via oral and intravenous administration has been shown to be similar between adult, including the elderly, and adolescent patients.¹⁹¹ Tedizolid demonstrates high protein binding at approximately 90% and has a volume of distribution of greater than 100L.^{304,380} Metabolism of this agent predominantly occurs via conjugation and excretion by the liver as an inactive compound with the remainder, less than 20%, being excreted as unchanged drug in the urine.³⁸⁰ The elimination half-life in adults is approximately 11 hours for both the oral and intravenous formulations.^{304,380} Renal dosing adjustments are not required with this agent in patients exhibiting advanced renal failure, as the drug half-life and AUC of tedizolid were not significantly different between normal patient cohorts and patients in renal failure. Further, dosage adjustments are not required in patients receiving hemodialysis, as pharmacokinetics were not significantly impacted because this agent is not removed.³⁸⁰ The tedizolid adult dosing recommendation is 200 mg administered daily via either the oral or intravenous route.

Indications for Use

Phase II evaluation of tedizolid evaluated three different oral dosages (200, 300, or 400 mg) administered daily for 5 to 7 days in adult patients with suspected or confirmed complicated skin and skin structure infection. A daily 200-mg oral dose was determined to be the lowest effective dose for the treatment of complicated skin and skin structure infection.²⁸⁴ During a phase III clinical trial enrolling adult patients with acute bacterial skin and skin structure infections, a 6-day course

of oral tedizolid phosphate proved to be non-inferior to a 10-day course of oral linezolid with early and sustained clinical response rates that were similar between groups.²⁸⁵ Similarly, a phase III clinical trial enrolling patients older than 12 years with acute bacterial skin and skin structure infections found a 6-day course of intravenous tedizolid phosphate to be non-inferior to a 10-day course of linezolid.²⁴⁷ With these data, tedizolid phosphate received FDA approval for the treatment of acute bacterial skin and skin structure infections in adults. A phase III study is underway to compare the safety of intravenous to oral tedizolid (200 mg) for 6 days versus a 10-day course of comparator antibiotic agents in adolescent patient (12 to <18 years of age) with complicated skin and soft tissue infection (NCT02276482). A phase III study is investigating intravenous tedizolid for the treatment of ventilated adult patients with presumed gram-positive hospital-acquired bacterial pneumonia or ventilator-associated bacterial pneumonia (NCT02019420).

Adverse Effects

Data from multiple trials indicate that tedizolid is safe and well tolerated, with the majority of adverse events across studies being reported as either mild or moderate. Prokocimer and colleagues reported the most commonly experienced adverse events included nausea, diarrhea, vomiting and headache. No patients were found to have significant alterations in hematologic parameters, including platelet and neutrophil counts, or changes in electrocardiograms.²⁸⁴ In two phase III studies, fewer patients in the tedizolid groups had decreases in platelet count, neutrophil count or hemoglobin levels that were below the lower limit of normal as compared to patients in the linezolid groups.^{247,285,323} However, additional experience with tedizolid is required to more appropriately assess differences in the risk of myelosuppression between tedizolid and linezolid, as studies to date have not been adequately powered to fully investigate this issue.

Rifamycins

The rifamycins are a group of complex macrocyclic antibiotics that were isolated from *Streptomyces mediterranei* in the early 1960s. Rifampin (rifampicin) and rifabutin are structurally related, semisynthetic broad-spectrum antibiotics derived from rifamycin B and S, respectively. These agents avidly bind to the subunit of the DNA-dependent RNA polymerase, prevent attachment of the enzyme to DNA, and thus block initiation of RNA transcription and protein synthesis. Rifabutin was approved in 1992 for prevention of disseminated MAC disease in adults with advanced HIV infection. Single-point mutations that determine resistance develop rapidly when rifamycins are used alone. Therefore, these antibiotics should be administered in combination with other antimicrobial agents when indicated. Rifaximin also is a semisynthetic derivative of rifamycin that was approved by the FDA in 2004 for the treatment of individuals 12 years of age or older who have nondysenteric and afebrile traveler's diarrhea caused by noninvasive strains of *E. coli*.⁴

In Vitro Activity

Rifampin usually is bactericidal, but it may be bacteriostatic, depending on the organism and drug concentration. Rifamycins have excellent in vitro activity against many gram-positive cocci, including many methicillin-resistant staphylococci and penicillin-nonsusceptible *S. pneumoniae* (enterococci are notable exceptions); some gram-negative organisms, including meningococci, gonococci, and *H. influenzae*; *Legionella*; *C. trachomatis*; *T. gondii*; *M. tuberculosis*; and *M. leprae*. Rifampin is active against *Mycobacterium kansasii*, but not against most other species of atypical mycobacteria. In contrast, rifabutin is active against most atypical mycobacteria, except *M. chelonae*. Rifabutin also is more active than rifampin against rifampin-susceptible strains of *Mycobacterium tuberculosis* and is active against approximately one third of rifampin-resistant strains.^{219,244} Resistance to rifampin is mediated by point mutations in the *rpoB* gene that encodes the subunit of the DNA-dependent RNA polymerase, as well as alterations in membrane permeability. Surveillance data documented that 3% of meningococcal isolates in the United States are resistant to rifampin.¹⁸⁵ Rifaximin has activity against most enteric bacterial pathogens, including *C. difficile*, *C. jejuni*, *E. coli*, *H. pylori*, *Salmonella* spp., *Shigella* spp., *V. cholera*, and *Yersinia enterocolitica*.⁴

Pharmacokinetics

Rifampin and rifabutin are highly lipid soluble and highly protein bound molecules (72% to 89%). Consequently, they are well absorbed from the gastrointestinal tract and have excellent intracellular penetration. The drugs reach therapeutic concentrations in the CSF (\approx 10% to 20% of simultaneous serum concentrations), particularly in the presence of inflammation of the meninges. They are metabolized primarily by the liver through deacetylation, and 30% to 40% of the drug is excreted by the biliary system. In the presence of hepatic dysfunction, dosage adjustments are necessary, whereas no alteration in dosage is required for children with renal dysfunction. In adults, rifabutin has a significantly longer mean terminal half-life than rifampin (45 vs. 2 to 5 hours).²⁹¹ Rifampin, however, has a very long postantibiotic effect. Rifaximin is poorly absorbed, with a bioavailability of less than 0.4%. Therefore, dosage adjustment of rifaximin for hepatic or renal dysfunction is not necessary, and the agent is unlikely to interact with medications metabolized by the CYP450 system.

Indications for Use

The only situation in which rifampin should be considered for use as a single antibacterial agent is for prophylaxis of infection, because resistance to rifampin can develop rapidly when this agent is used alone for therapeutic purposes. Prophylaxis with rifampin monotherapy is indicated to eradicate nasopharyngeal colonization in close contacts of individuals with infections caused by *H. influenzae* type b^{138,251} and *N. meningitidis*,³³ as well as index cases with these infections, unless they were treated with third-generation cephalosporins.

The use of rifampin, combined with two or three other bactericidal antituberculosis agents for the treatment of active tuberculosis, as well as its combined use with clofazimine and dapsone for the treatment of leprosy, is considered an essential component of effective regimens. The effect of adding rifampin to certain antibiotics for treatment of other infections often is unpredictable and may result in synergistic, additive, indifferent, or antagonistic activity. In some patients, rifampin can be considered part of a combination regimen for the treatment of (1) meningitis caused by penicillin- and cephalosporin-resistant *S. pneumoniae* in combination with a third-generation cephalosporin and vancomycin; (2) shunt- or catheter-associated staphylococcal infections, often with removal of the foreign material; (3) *S. aureus* implant-related orthopedic infections in combination with an effective agent; (4) non-life-threatening susceptible MRSA skin and skin structure infections in combination with TMP-SMX with the theoretical benefit of eradicating MRSA carriage, considering that rifampin achieves high concentrations on mucosal surfaces; (5) prosthetic valve endocarditis caused by staphylococci; (6) complicated or severe *B. henselae* infection (cat-scratch disease); (7) brucellosis in combination with TMP-SMX, a tetracycline, or an aminoglycoside²²³; (8) MAC-associated disseminated disease or lymphadenitis, if not completely resectable, in combination with ethambutol and azithromycin or clarithromycin; (9) *L. pneumophila* pneumonia in combination with a macrolide if response to macrolides alone is poor; and (10) multidrug-resistant *S. maltophilia* in combination with colistin (i.e., colistimethate sodium or polymyxin E) based on favorable in vitro data.^{185,219} Furthermore, rifampin and minocycline-impregnated central venous catheters have been used successfully in adults to prevent catheter colonization and bloodstream infection with gram-positive and gram-negative pathogens, as well as with *Candida* spp. Data regarding the use of these catheters in children is limited.²⁶⁹ Many physicians use rifampin combined with antistaphylococcal agents for treatment of disseminated MRSA infection without evidence from controlled studies of its effectiveness.

Rifabutin is effective for the treatment of most mycobacterial species, *H. pylori*, and *T. gondii* in adults. Limited data are available for the treatment of MAC infections in children with HIV infection. Clinical studies in adults with advanced HIV infection indicate that administration of daily clarithromycin or weekly azithromycin is superior to rifabutin alone for prophylaxis of MAC infection.²⁴⁴ The use of rifabutin as an alternative to azithromycin or clarithromycin for prophylaxis of MAC infection in children is limited by drug interactions and lack of efficacy data.⁷³

Rifampin is available in capsule (150 and 300 mg) and intravenous formulations. Rifabutin is available only in capsule (150 mg) form. A

suspension can be compounded by the pharmacy, or the capsule contents can be mixed with thick, sweet food for infants and young children. Absorption of rifampin is optimal if administered 1 hour before or 2 hours after a meal, whereas a high-fat meal decreases the rate, but not the total amount, of absorption of rifabutin. The use of fixed-dose combinations of rifampin, isoniazid, and pyrazinamide is not recommended for children. Although the safety and efficacy of rifapentine, a rifamycin antibiotic similar in structure and activity to rifampin and rifabutin, have not been established for children younger than 12 years of age, a pharmacokinetic study indicated that dosages in children need to be greater than those for adults to achieve comparable systemic exposure.³⁶ Combination treatment with rifapentine and isoniazid given once weekly for 3 months for the treatment of latent tuberculosis infection was found to be as effective as daily therapy with isoniazid alone, safe and associated with a higher treatment completion rate in children 2 to 17 years of age.³⁶⁴ The approved dosage of rifaximin for the treatment of traveler's diarrhea in adolescents and adults is 200 mg three times per day for 3 days. A dosage of 400 mg twice per day for 3 days apparently is equally effective and may be better tolerated by patients. Rifaximin should not be used to treat systemic infections or mucosally invasive enteric infections. Rifaximin is not indicated currently for the treatment of dysenteric diarrhea secondary to *Shigella*, *Salmonella*, or *Campylobacter* spp. infection or for the treatment of complicated diarrhea with fever, systemic toxicity, or bloody stools. The role of this agent for prophylaxis of traveler's diarrhea is being studied.^{4,17}

Adverse Effects

Adverse events associated with rifampin include gastrointestinal disorders, rash, hepatotoxicity, hypersensitivity, and a flulike syndrome. Adverse reactions to rifabutin include gastrointestinal disorders, rash, leukopenia, neutropenia, and, rarely, uveitis, although safety data in children are limited. The parenteral form of rifampin is associated with thrombophlebitis. Routine determination of serum aminotransferase concentrations is not recommended for children receiving brief or prolonged courses of therapy, except for those with clinical evidence of hepatitis or severe or disseminated tuberculosis. In these situations, at least monthly measurements should be performed. In addition, patients should be warned that rifamycins discolor urine, tears, sweat, and feces and permanently stain soft contact lenses. Because rifamycins induce hepatic CYP450 enzyme activity, they may interact with other medications administered concurrently and cause decreased concentrations of some antiretroviral agents, particularly protease inhibitors, azole antifungal agents, barbiturates, oral contraceptives, clarithromycin, cyclosporine, digoxin, sulfonylureas, thyroxine, and warfarin (Coumadin). Conversely, rifamycin serum drug concentrations may increase if it is administered with other drugs that inhibit hepatic enzymes, and the dose of rifamycin antibiotic may need to be reduced by as much as 50%. Rifabutin induces hepatic enzymes to a lesser extent than does rifampin and therefore has less potential for drug interactions.^{219,244} Rifaximin is well tolerated and has an excellent safety profile.

Antibiotics Interfering With Protein Synthesis Not Approved for Use in Children

Fidaxomicin is a macrocyclic antibiotic isolated from the fermentation broth of *Dactylosporangium aurantiacum* that inhibits the bacterial sigma subunit involved in protein synthesis. It has a narrow spectrum of activity with bactericidal effect against gram-positive anaerobes, including *C. difficile*, and demonstrated activity for the NAP1/B1/027 strain. It received FDA approval in 2011 for treatment of *C. difficile*-associated diarrhea in adults. Fidaxomicin was shown to be non-inferior to vancomycin for the treatment of *C. difficile* infection and was effective in preventing recurrences. It has minimal systemic absorption and appears to be well tolerated.^{92,114,368}

AGENTS THAT TARGET NUCLEIC ACID

Fluoroquinolones

Fluoroquinolone antibiotics are derivatives of nalidixic acid. In contrast to nalidixic acid, fluoroquinolones have (1) a broader spectrum of activity that includes aerobic gram-negative enteric organisms, particularly Enterobacteriaceae, *Haemophilus* spp., *Neisseria* spp., *M. catarrhalis*,

nonenteric gram-negative bacilli such as *P. aeruginosa*, oxacillin-susceptible staphylococci, some streptococci, bacteria associated with atypical pneumonia, certain genital pathogens, and certain strains of mycobacteria; (2) better penetration into tissues; (3) good intracellular penetration; and (4) rapid bactericidal activity.

Mechanisms of Action

Fluoroquinolones are the only class of antibacterial agents in clinical use that directly inhibit DNA synthesis. They bind to bacterial DNA gyrase and topoisomerase IV. Inhibition of bacterial gyrase causes relaxation of the supercoiled DNA that leads to termination of chromosomal replication and interference with cell division and gene expression. Inhibition of the activity of topoisomerase IV leads to separation of two united DNA molecules and subsequent interference with cellular replication.

Mechanisms of Resistance

A growing concern is that widespread use of fluoroquinolones among adult populations has been associated with resistance rates, especially among Enterobacteriaceae, that exceed 50% in some regions. Mechanisms of resistance include chromosomal mutations in genes that encode fluoroquinolone target enzymes (i.e., DNA gyrase and topoisomerase IV), efflux pumps, or porin (i.e., outer-membrane diffusion) channels. Identified plasmid-mediated resistance determinants in strains of *K. pneumoniae*, *E. coli*, *Enterobacter*, and other enteric bacteria include (1) Qnr, a protein that protects DNA gyrase from quinolone action and is associated with multidrug resistance and (2) a variant of the aminoglycoside acetyltransferase found in gram-negative bacteria that is capable of inactivating ciprofloxacin.^{212,300} Fluoroquinolone-resistant strains of *N. gonorrhoeae* are common findings in many parts of the world and are spreading in the United States, especially in California and Hawaii. The CDC no longer recommends fluoroquinolones for treatment of gonorrhea in the United States.³⁷⁰ Other bacteria with increasing rates of resistance include *S. pneumoniae* and intestinal pathogens such as *Campylobacter jejuni*, *Shigella* spp., *Salmonella* spp., certain strains of *Klebsiella pneumoniae*, *E. coli*, and *P. aeruginosa*, among others.⁹

In Vitro Activity

Levofloxacin and moxifloxacin have greater potency than ciprofloxacin against gram-positive cocci, and moxifloxacin has enhanced activity against anaerobic bacteria, although in some series, approximately 50% of invasive *Bacteroides* spp. are resistant to moxifloxacin.¹³³ Ciprofloxacin remains the most potent marketed fluoroquinolone against gram-negative bacteria, particularly against some strains of *P. aeruginosa*, *Providencia* spp., *Proteus* spp., and *S. marcescens*. In vitro studies of newer and investigational fluoroquinolones against penicillin and cephalosporin-resistant pneumococci indicate excellent activity, whereas activity of ciprofloxacin, norfloxacin, and ofloxacin is limited. Fluoroquinolone use for MRSA and oxacillin-resistant, coagulase-negative staphylococci is limited because resistant mutants can be selected relatively easily, thus leading to treatment failure and relapse. Constitutive high-level resistance exists among MRSA isolates from patients with CAMRSA infections in some areas of the United States. Although MICs tend to be lower for newer (e.g., moxifloxacin and gatifloxacin) in contrast to older (e.g., ciprofloxacin and levofloxacin) fluoroquinolones, genes conferring fluoroquinolone resistance in *S. aureus* confer resistance to the entire class of agents.¹³⁶ Activity against enterococci is marginal or absent. Fluoroquinolones are effective against atypical pneumonia pathogens (i.e., *Chlamydia pneumoniae*, *L. pneumophila*, and *M. pneumoniae*) and certain genital pathogens (i.e., *C. trachomatis*, *U. urealyticum*, and *Mycoplasma hominis*). Ciprofloxacin, levofloxacin, and moxifloxacin are active in vitro against certain strains of *M. tuberculosis*, *Mycobacterium fortuitum*, *M. kansasii*, and *M. chelonae* and are less active against MAC. No quinolone antibiotic has been shown to be active against *T. pallidum*.

Pharmacokinetics

The fluoroquinolones generally have excellent bioavailability that is not substantially affected by food, with values of 70% for ciprofloxacin, 85% for moxifloxacin, and greater than 95% for ofloxacin and

levofloxacin. These drugs have large volumes of distribution, and they concentrate in the kidneys and in urine (except moxifloxacin, which undergoes hepatic metabolism and biliary excretion). This class of agents has favorable pharmacokinetic properties in children, and their efficacy correlates best with the 24-hour AUC/MIC ratio because of a combination of concentration-dependent killing and postantibiotic effect. These properties suggest that large doses given at relatively infrequent intervals would be most effective.³¹⁵ However, based on pharmacokinetic studies, doses for patients with cystic fibrosis should be higher and more frequent than for patients without cystic fibrosis, and the dosage should be decreased in proportion to increasing body weight. Fluoroquinolones can interact with a variety of other drugs, including caffeine, cyclosporine, dideoxyinosine, nonsteroidal antiinflammatory drugs, theophylline, and other agents that prolong the QT interval. Coadministration with antacids, ferrous sulfate, and multivitamins containing zinc can reduce oral bioavailability.

Indications for Use

Fluoroquinolones have been used extensively in adults for the treatment of skin and soft tissue, skeletal, and intra-abdominal infections, as well as infections of the urogenital, gastrointestinal, and respiratory tracts. Fluoroquinolones commonly used in adults include the second-generation agents ciprofloxacin and levofloxacin and the fourth-generation agent moxifloxacin. Other agents with limited indications include ofloxacin, norfloxacin (second generation), and gemifloxacin (third generation). Four agents have been withdrawn from the market in the United States: gatifloxacin, grepafloxacin (causes cardiac toxicity), sparfloxacin, and trovafloxacin (causes hepatotoxicity). Ciprofloxacin, levofloxacin, and moxifloxacin are FDA approved for the treatment of uncomplicated skin infections caused by susceptible organisms in adults. However, none of these fluoroquinolones are FDA approved for treatment of MRSA infections.

Use in pediatric patients has been limited because of the potential for inducing cartilage damage that leads to arthropathy, as demonstrated in juvenile animal studies. However, no convincing evidence exists that quinolone-induced arthropathy occurs in humans. Reversible arthralgia and tendinopathy have a temporal association with fluoroquinolone use. Fluoroquinolones are not approved for use in children and adolescents younger than 18 years, except in the following situations: (1) complicated urinary tract infections and pyelonephritis attributable to *E. coli* in children 1 year of age and older (approved by the FDA in 2004) and (2) exposure to aerosolized *B. anthracis* to prevent onset or progression of disease. However, these drugs have been used in certain clinical settings, such as cystic fibrosis, primarily because they are the only oral antibiotics with activity against *P. aeruginosa*. Furthermore, ciprofloxacin and levofloxacin are available in suspension formulations. In 2002 alone, approximately 500,000 prescriptions for fluoroquinolones were written in the United States for individuals younger than 18 years old.⁹ These agents, particularly ciprofloxacin, have been used to treat exacerbations of chronic pseudomonal pulmonary infections in patients with cystic fibrosis; complicated urinary tract infections caused by multidrug-resistant bacteria; chronic suppurative otitis media associated with *P. aeruginosa*; osteochondritis attributable to *P. aeruginosa*; shigellosis, *C. jejuni*, and other bacterial causes of enteritis; multidrug-resistant typhoid fever; cholera; infections in neutropenic patients with cancer; in combination with other agents to treat multidrug-resistant mycobacterial disease; and multidrug-resistant gram-negative bacillary septicemia or meningitis (no controlled trials in children with meningitis have been reported using currently licensed agents).^{9,66,308,316} Fluoroquinolones also effectively eradicate nasopharyngeal carriage of susceptible meningococci. One study showed that children with acute otitis media and otorrhea through tympanostomy tubes had better clinical outcomes with fewer adverse effects when they were treated with ciprofloxacin-dexamethasone otic suspension in contrast to high-dose amoxicillin-clavulanic acid suspension.¹⁰³ Although gatifloxacin is not approved for use in children and currently is not available in the United States, noncontrolled studies confirmed that it is safe and effective for treatment of recurrent acute otitis media and acute otitis media when therapy with standard antimicrobials has failed.²⁷⁹

The current recommendation is that parenteral and oral fluoroquinolones should be reserved for situations in which no effective, safe,

and nonrestricted alternative antimicrobial agents are available to treat complicated or multidrug-resistant bacterial infections. Appropriate uses should be limited to the following clinical situations: exposure to aerosolized *B. anthracis*; urinary tract infections caused by *P. aeruginosa* or other multidrug-resistant, gram-negative bacteria; chronic suppurative otitis media or malignant otitis externa caused by *P. aeruginosa*; acute or chronic osteomyelitis or osteochondritis caused by *P. aeruginosa*; exacerbations of pulmonary disease in patients with cystic fibrosis who have *P. aeruginosa* colonization and for whom oral therapy is appropriate; susceptible mycobacterial infections as part of a combination regimen; gram-negative bacterial infections in immunocompromised hosts in whom oral therapy is appropriate or resistance to alternative agents is present; gastrointestinal infections caused by multidrug-resistant *Shigella* spp., *Salmonella* spp., *V. cholera*, or *C. jejuni*; and proved bacterial septicemia or meningitis caused by multidrug-resistant pathogens that are susceptible only to fluoroquinolones, that have failed to respond to approved agents, or that require use of a fluoroquinolone because of life-threatening hypersensitivity to alternative agents.⁹

Adverse Effects

Adverse events associated with fluoroquinolone therapy occur in 3% to 17% of adult and pediatric patients and cause discontinuation of treatment in 1% to 2%. The most common reactions are gastrointestinal, minor CNS disorders, and allergic rashes.³¹⁵ Other infrequent adverse reactions include photosensitivity; disorders of glucose homeostasis; prolongation of the QT interval, with rare cases of torsades de pointes, particularly among patients with long QT syndrome; leukopenia; and anaphylactoid reactions. Reversible tendonitis and tendon rupture occur uncommonly in adults.

Sulfonamides

Sulfonamides, discovered in the 1930s, are broad-spectrum antimicrobial agents derived from sulfanilamide (*p*-aminobenzene sulfonamide) and are structural analogues of *p*-aminobenzoic acid (PABA); they compete with PABA and result in interference with nucleotide synthesis. Sulfanilamide was manipulated to form other compounds with expanded antimicrobial activity and reduced toxicity. Sulfonamides are distributed widely in fluids and tissues. The preparations currently available have greater solubility than earlier compounds and are less likely to cause crystalluria. Sulfadiazine is available for single-agent use. Sulfonamide combinations, including trimethoprim-sulfamethoxazole (TMP-SMX) and erythromycin ethylsuccinate-sulfisoxazole acetyl (EES-SSX), are used frequently in pediatrics.

Trimethoprim-Sulfamethoxazole

TMP is a diaminopyrimidine antibiotic available for single-agent use. Combinations of TMP and sulfonamides were used in the late 1960s because of presumed synergistic antibacterial activity, although clinical evidence of synergy is equivocal. Because SMX has rates of absorption and elimination similar to those of TMP, it was the sulfonamide selected for combination. Iclaprim is a novel diaminopyrimidine with a broad spectrum of activity that includes TMP-resistant strains of *S. aureus* (including MRSA and vancomycin-resistant *S. aureus*), *S. pneumoniae* (including penicillin-nonsusceptible strains), *P. jiroveci*, *Neisseria*, *M. catarrhalis*, and *C. pneumoniae*.¹⁴⁹ Iclaprim inhibits bacterial dihydrofolate reductase; it has been evaluated in clinical trials, including a multicenter, double-blind, phase II, randomized study comparing safety and efficacy with vancomycin but has not been approved by the FDA.²⁰¹

Mechanisms of action. SMX competitively inhibits dihydropteroate synthetase, the bacterial enzyme that assimilates PABA into dihydrofolic acid; such inhibition results in a reduction in dihydrofolic acid synthesis and therefore a reduction in the amount of tetrahydrofolic acid, a cofactor for nucleotide synthesis.¹⁵¹ Only bacteria that must synthesize folic acid are potentially susceptible. SMX is bacteriostatic when used alone and can be inhibited by PABA and its derivatives (procaine and tetracaine). TMP reversibly binds and inhibits dihydrofolate reductase, an enzyme that reduces dihydrofolic acid to tetrahydrofolic acid; this activity results in diminished amounts of folic acid, an essential cofactor in nucleic acid production.⁶² TMP is bacteriostatic when used alone, but in combination with SMX against susceptible bacteria, bactericidal activity

can be achieved by blockade of sequential steps in folic acid metabolism. The effect of sulfonamide on bacteria is circumvented in mammals, which obtain folate from food sources. The reaction inhibited by TMP is similar in bacteria and mammals but differs quantitatively in the extent of binding of the drug to the enzyme; mammalian dihydrofolate reductase is 60,000 times less sensitive to TMP than is the enzyme in susceptible bacteria.

Mechanisms of resistance. Bacteria can be inherently resistant to either agent or can acquire resistance to TMP, SMX, or both agents. Resistance to SMX and other sulfonamides is associated with hyperproduction of PABA, as demonstrated in strains of *Neisseria* and staphylococci, or is caused by an altered dihydropteroate synthetase enzyme with lower affinity for sulfonamides, as found in *E. coli*, *N. meningitidis*, and *S. pneumoniae*.³⁴⁶ Chromosomally mediated resistance to TMP on the basis of mutations in the *dhfr* gene has been observed in strains of *S. pneumoniae*, *H. influenzae*, *E. coli*, *Pediococcus*, *B. fragilis*, and *Nocardia* and *Clostridium* spp. Furthermore, *P. aeruginosa*, *K. pneumoniae*, and *S. marcescens* are inherently resistant to TMP because of cell wall impermeability. Acquired resistance to TMP can be plasmid-mediated or chromosomally mediated and occurs in members of the Enterobacteriaceae and in staphylococci and streptococci. Mechanisms of acquired TMP resistance include cell wall impermeability, thymine auxotrophy, resistant dihydrofolate reductase, and overproduction of dihydrofolate reductase, the most common being plasmid-mediated production of dihydrofolate reductases, which are encoded by at least 20 genes. Resistance to sulfonamides is encoded by the *dhps* family of genes that include the *folP* and *sulI* and *sulII* genes. The *sulI* gene usually is linked to other transferable resistance genes, often in the transposons that belong to the *Tn21* family. Despite the reduced use of sulfonamides, the genetic determinants for sulfonamide resistance probably persist because of the efficient integron transfer mechanisms.¹⁶¹ Bacterial resistance to both TMP and SMX can develop as a result of altered cell wall permeability or alternative metabolic pathways (e.g., thymine auxotrophy), whereby they obtain thymine or thymidine from the environment.³⁴⁶

In vitro activity. TMP-SMX has activity against a broad spectrum of gram-positive cocci and gram-negative enteric pathogens. TMP is more active than the sulfonamide, but the mixture is significantly more effective than either drug alone. Synergism is more likely to occur when the bacteria are susceptible to both drugs, but it can occur even when the bacteria are resistant to only one agent. Bacteria with potential susceptibility to the combination include *Aeromonas hydrophila*, *Brucella*, *B. cepacia*, *Campylobacter*, *E. coli*, *H. influenzae*, *M. catarrhalis*, *Kingella kingae*, some environmental mycobacteria, *N. gonorrhoeae*, *Nocardia*, *P. jiroveci*, *Proteus*, *Salmonella*, *S. marcescens*, *Shigella*, oxacillin-susceptible and methicillin-resistant *S. aureus*, *S. maltophilia* (usually with a β -lactam-lactamase inhibitor combination), penicillin-susceptible *S. pneumoniae*, and *Yersinia enterocolitica*. However, high levels of resistance to TMP-SMX among strains of penicillin-nonsusceptible *S. pneumoniae*, *M. catarrhalis*, *H. influenzae*, *Neisseria*, *E. coli*, *Klebsiella*, *Salmonella*, *Shigella*, *Campylobacter*, *P. aeruginosa*, *Acinetobacter*, *Actinomyces*, mycobacteria, *Bacteroides*, *Clostridium*, and *C. pneumonia* limit the usefulness of this antibacterial agent.¹⁶¹

Pharmacokinetics. Optimal synergistic activity occurs when a 1:20 ratio of TMP and SMX serum concentrations is attained, as can be achieved after the administration of a fixed 1:5 ratio of TMP to SMX. Both agents are absorbed rapidly and fairly well when administered alone and in combination. Both penetrate most body fluids and tissues, although TMP frequently penetrates extravascular tissues to a greater degree than SMX. Both agents cross the placenta, are excreted in breast milk, and diffuse into pleural, peritoneal, and synovial fluid and CSF. Protein binding varies from 40% to 60% for TMP and from 60% to 70% for SMX. Both drugs are metabolized in the liver to inactive metabolites. The primary route of elimination is by the kidneys, with small amounts excreted in bile and feces. Dosage adjustments are required for renal impairment.

Available preparations include an oral suspension containing 40 mg of TMP and 200 mg of SMX per 5 mL, tablets containing 80 mg of TMP and 400 mg of SMX, double-strength tablets consisting of 160 mg of TMP and 800 mg of SMX, and a parenteral solution.

Indications for use. TMP-SMX is approved for the treatment of acute exacerbations of chronic bronchitis in adults, enterocolitis caused by susceptible *Shigella* organisms, acute otitis media caused by susceptible strains of *H. influenzae* or pneumococcus, *P. jiroveci* pneumonia, traveler's diarrhea caused by *Shigella* and enterotoxigenic *E. coli*, and acute or chronic urinary tract infections. Although the combination is not approved for use and not usually prescribed as a first-line antibiotic, TMP-SMX has been effective therapy for typhoid fever, brucellosis, nocardiosis, sinusitis, biliary tract infections, and bone and joint infections caused by susceptible organisms. Because early studies did not evaluate the effect of prolonged or recurrent therapy on somatic growth or bone marrow function in children, TMP-SMX was not approved for prophylaxis or prolonged treatment of otitis media. It is not recommended for treatment of group A streptococcal tonsillopharyngitis because it does not eradicate the organism or reliably prevent the nonsuppurative sequelae. TMP-SMX is not recommended as first-line monotherapy for community-acquired pneumonia, acute otitis media, or skin infections caused by *S. pyogenes* because of frequent resistance among the etiologic pathogens and absence of efficacy data. TMP-SMX is not FDA approved for the treatment of any form of staphylococcal infection. However, the medical literature contains reports of the successful use of TMP-SMX alone or in combination with one or more agents such as rifampin in the treatment of *S. aureus* infections, including MRSA.^{136,163} TMP-SMX is recommended as an alternative agent to macrolides for treatment of pertussis in individuals 2 months of age or older.³⁵⁰ TMP-SMX also is an important prophylactic agent that is indicated to prevent bacterial, *P. jiroveci*, and other infections in the following clinical settings: immunosuppressed oncology or posttransplant patients, individuals with HIV who meet clinical and hematologic criteria or certain infants who are exposed in utero to HIV, patients with urinary tract infections who are at risk for recurrent disease, and patients with chronic granulomatous disease or other congenital immunodeficiency syndromes.

Adverse effects. Most of the side effects occurring during administration of TMP-SMX are caused by the sulfonamide. Gastrointestinal disturbances and hypersensitivity reactions are the adverse events most commonly observed. Anorexia, nausea, vomiting, diarrhea, drug eruption, and photosensitivity reactions can occur in 1% to 4% of patients. Hypersensitivity reactions that develop less frequently include erythema nodosum, erythema multiforme (including Stevens-Johnson syndrome), urticaria, anaphylaxis, and thyroid damage. Drug-induced hepatitis has been described but is an unusual event. CNS side effects include vertigo, ataxia, headache, and aseptic meningitis. TMP-SMX can affect renal function when it is administered to persons with underlying renal disease, but the side effect usually is reversible after discontinuation of therapy. Crystalluria occurred more commonly with earlier preparations because of low solubility. SMX has a greater tendency to cause crystalluria than other sulfonamides that are currently available, because of slower absorption and excretion. However, with adequate fluid intake, alkalization of the urine usually is unnecessary. Interstitial nephritis and tubular necrosis seldom are associated with the use of TMP-SMX. Blood dyscrasias can be a limiting factor to the administration of TMP-SMX. Acute hemolytic anemia has been described after the use of TMP-SMX in patients with glucose-6-phosphate dehydrogenase deficiency. Although they are uncommon in patients with normal hematopoietic systems, aplastic anemia, agranulocytosis, leukopenia, and thrombocytopenia can occur. Prolonged use can result in megaloblastic anemia because of impaired folate use. Administration of sulfonamide can trigger an acute attack of porphyria. Sulfonamides can displace bilirubin from albumin binding sites. In neonates, especially premature infants, the activity of sulfonamides can be increased as a result of reduced conjugation by the immature liver. Because of the increased risk for development of kernicterus from sulfonamide displacement of bilirubin, the use of sulfonamides during the last month of pregnancy and in the first 2 months of life is discouraged.

Drug-drug interactions with TMP-SMX are numerous. Sulfonamides can displace other drugs from albumin binding sites and thereby result in increased effective activity of the second drug, as can be seen with the concurrent administration of methotrexate, phenytoin, sulfonylurea hypoglycemic agents, thiazide diuretics, and warfarin. Drugs that, when coadministered, can displace sulfonamides from binding sites and lead

to increased effective sulfonamide activity include indomethacin, probenecid, and salicylates. Agents that reduce the effect of sulfonamides include methenamine, which results in insoluble urinary precipitates of the sulfonamide, and derivatives of PABA. Sulfonamides are physically incompatible with many drugs, among them aminoglycosides, chloramphenicol, insulin, lincomycin, methicillin, tetracycline, and vancomycin.

Erythromycin Ethylsuccinate–Sulfisoxazole Acetyl

The combination of EES and SSX in a fixed ratio expands the spectrum of antibacterial activity. The mechanism of action, mechanisms of resistance, pharmacokinetics, and adverse events for EES-SSX are the same as those for each individual drug. Because EES-SSX is effective in vitro against common pathogens causing otitis media in children, it was approved for the treatment of acute otitis media.⁴⁵ However, it is not effective against many strains of pneumococci and no longer is recommended for empirical therapy of acute otitis media.¹¹ Although it is not approved for use, it can be effective therapy for sinusitis caused by *H. influenzae*, susceptible pneumococci, and *M. catarrhalis*. Albeit uncommon, its principal use today in pediatrics is for the treatment of acute otitis media caused by susceptible pathogens in patients with β -lactam hypersensitivity.

Metronidazole

Metronidazole is a synthetic imidazole available since 1959. It was first introduced for the treatment of *Trichomonas vaginalis*. Metronidazole has antiprotozoal and anaerobic activity.

Mechanisms of action. Metronidazole enters the cells by passive diffusion, and the nitro side chain undergoes chemical reduction by the pyruvate-ferredoxin reductase complex into a toxic nitro radical that subsequently causes DNA destabilization and rupture with cell death. It has been postulated that metronidazole has antiinflammatory and immunomodulator effects by decreasing neutrophil generation of hydrogen peroxide and hydroxyl radicals.

Mechanisms of resistance. Bacteria become resistant to metronidazole by changes in the enzymes implicated in the activation of the antibiotic. Some bacteria contain *nim* genes that code for an inactivating enzyme that reduces the nitro group into an inactive amine. These genes may be present in plasmids and chromosomes.

Pharmacokinetics. Metronidazole has good oral absorption with a bioavailability of at least 90%. It is available in oral (i.e., tablets and capsules) and parenteral forms. It is also available for topical use (i.e., vaginal and rectal). It has good penetration and a low degree of protein binding (<20%), for which it has wide distribution, including good concentrations in CSF. Its half-life is approximately 8 hours. Metronidazole is eliminated mainly by renal clearance (60% to 80%), and 6% to 15% is eliminated unchanged in feces. It is cleared by hemodialysis but does not require dose adjustment with renal insufficiency. In cases of severe hepatic dysfunction, the dose should be adjusted secondary to reduced clearance.

Indications for use. Metronidazole is the treatment of choice for *T. vaginalis*, *Giardia duodenalis*, *Entamoeba histolytica*, bacterial vaginosis, and *C. difficile*-associated disease. Metronidazole has been widely used in pediatrics for the treatment of anaerobic infections, including intra-abdominal and head and neck infections (including brain abscess), despite its lack of FDA approval for these indications. For these infections a combination regimen should be used because metronidazole does not have aerobic activity. Metronidazole is used for the treatment of *H. pylori* ulcerative disease, in combination with other antibiotics and a proton pump inhibitor.²²⁰ Safety and effectiveness of metronidazole in children have not been established, except for the treatment of amebiasis with oral metronidazole.

Adverse effects. Gastrointestinal disturbances are the most frequent adverse effects, including nausea and diarrhea. Less frequently, dizziness, headache, loss of appetite, emesis, and abdominal pain have been reported. Other rare effects include taste changes, constipation, dry mouth, glossitis or stomatitis, headache, dark urine, pruritus, rash, insomnia, arthralgias, fever, and reversible hematologic disturbances, including leukopenia and thrombocytopenia. The parenteral form may cause phlebitis at the site of injection. With high doses, neurologic

effects may be seen, including ataxia, confusion, and irritability.⁴⁷ The neurologic side effects require discontinuation of the drug. In older patients, the concomitant consumption of metronidazole and alcohol can produce a disulfiram effect.

SELECTED ASPECTS OF THE ADMINISTRATION OF ANTIMICROBIAL AGENTS

Dosage Schedules for Infants and Children

Dosage schedules of antimicrobial agents commercially available in the United States for infants (beyond the newborn period) and children are listed in Table 236.4. The list is subdivided into dosage schedules for mild-to-moderate and for severe disease. Oral regimens are used for mild-to-moderate infections caused by susceptible organisms in areas that are well vascularized and in which adequate concentrations of drug are achieved at the site of infection. Parenteral administration should be considered for severe infections, especially those caused by less susceptible organisms that produce disease in areas in which diffusion of drug is limited.

Dosage Schedules for Newborn Infants

The clinical pharmacology of antimicrobial agents administered to newborn infants is unique and cannot be extrapolated from data derived from older children or adults. The physiologic and metabolic processes that affect the distribution, metabolism, and excretion of drugs undergo rapid changes during the child's first few weeks of life. The increased efficiency of kidney function after the infant's first 7 days requires an increase in dosage and a decrease in the interval between doses of penicillins and aminoglycosides for maintaining therapeutic concentrations of drug in blood and tissues. Thus, different dosage schedules are provided for the first week of life and for the subsequent weeks of the neonatal period (Tables 236.5 and 236.6). With survival of premature infants with very low birth weights, more data are needed on the use of antimicrobial agents in these infants with immature metabolic and physiologic mechanisms.²⁸² Dosages of antibiotics in these preterm infants, especially those weighing less than 1000 g, are unclear for many agents, and measurement of serum concentrations should be considered for drugs such as vancomycin and the aminoglycosides.

Should Dosages Be Determined by Weight or by Surface Area?

In most standard pediatric texts and in the package inserts prepared by manufacturers, dosages of antibiotics for children are based on body weight. Body surface area correlates more closely with extracellular fluid volume. Some investigators suggest that more predictable serum concentrations can be achieved by using calculations of dosages based on surface area than by using those based on weight.¹⁵⁰ This method may be more reliable for drugs that are distributed in extracellular fluid, such as aminoglycosides, especially when they are prescribed for obese or malnourished children. Currently, however, the convenience of calculating dosage on the basis of weight appears to be the more important consideration.

Use of Oral Preparations for Serious Infections

Oral preparations of antimicrobial agents vary in their degree of absorption within and between individuals, depending on the illness being treated and the formulation used. Because higher and more consistent serum concentrations of drug are achieved after parenteral administration, parenteral routes are preferable for serious infections. Sequential parenteral-oral antimicrobial therapy may be an option in patients with uncomplicated pneumonia, pyelonephritis, or intra-abdominal, skin and soft tissue, or suppurative skeletal infections.²³⁶ Results of studies of orally administered antibiotics in children with skeletal infections indicate that this mode of administration can be used successfully for a portion of the therapeutic course.^{260,345}

Specific guidelines for oral treatment of serious infections are recommended: (1) the patient should be able to swallow and retain the medication; (2) the dosage should be sufficiently large to provide adequate bactericidal concentrations of drug at the site of infection for at least 50% of the dosing interval for β -lactams; and (3) when possible, it is

TABLE 236.4 Daily Dosage Schedules for Antimicrobial Agents in Pediatric Patients Beyond Newborn Period

Agent, Generic (Trade Name)	Route	Mild-to-Moderate Infections ^a	Severe Infections ^a
Penicillin G, crystalline (numerous)	IV, IM	100,000–250,000 U ÷ into 4 doses	250,000–450,000 U ÷ into 6 doses
Penicillin G, procaine (numerous)	IM	50,000 U once daily (congenital syphilis); 300,000 (<60 lb) or 600,000–1,000,000 U (≥60 lb) ÷ into 1 or 2 doses for group A streptococcal infections	Inappropriate
Penicillin G, benzathine (Bicillin)	IM	300,000–600,000 U (<60 lb) ^b or 900,000 U (≥60 lb) ^b for group A streptococcal infections; 50,000 U/kg (up to 2,400,000 U) ^b for syphilis	Inappropriate
Penicillin V, phenoxymethyl penicillin (numerous)	PO	25–50 mg ÷ into 3 or 4 doses	Inappropriate
Penicillinase-resistant Penicillins			
Dicloxacillin	PO	25–50 mg ÷ into 4 doses	Inappropriate
Nafcillin (Nallpen)	IV, IM	50–100 mg ÷ into 4 doses	100–200 mg ÷ into 4 to 6 doses
Oxacillin (Bactocill)	IV, IM	100–150 mg ÷ into 4 doses	150–200 mg ÷ into 4 to 6 doses
Aminopenicillins			
Amoxicillin (numerous)	PO	25–90 mg ÷ into 2 or three doses	Inappropriate
Amoxicillin + clavulanate (Augmentin)	PO	45–90 mg ÷ into 2 or 3 doses	Inappropriate
Ampicillin (numerous)	IV, IM	100–200 mg ÷ into 4 doses	200–400 mg ÷ into 4 to 6 doses
	PO	50–100 mg ÷ into 4 doses	Inappropriate
Ampicillin + sulbactam (Unasyn)	IV	100–200 mg of ampicillin ÷ into 4 doses	200–400 mg of ampicillin ÷ into 4 to 6 doses
Extended-Spectrum Penicillins			
Piperacillin + tazobactam (Zosyn)	IV	Inappropriate	240–300 mg of piperacillin ÷ into 3 to 4 doses
Monobactams			
Aztreonam (Azactam)	IV, IM	90 mg ÷ into 3 doses	120 mg ÷ into 4 doses
Cephalosporins			
Cefadroxil (Duricef)	PO	30 mg ÷ into 2 doses	Inappropriate
Cefazolin (Ancef, Kefzol)	IV, IM	50 mg ÷ into 3 doses	50–100 mg ÷ into 3 or 4 doses
Cephalexin (Keflex, Kefab)	PO	25–100 mg ÷ into 4 doses	Inappropriate
Cefaclor (Ceclor)	PO	20–40 mg ÷ into 2 or three doses	Inappropriate
Cefoxitin (Mefoxin)	IV	Inappropriate	80–160 mg ÷ into 4 to 6 doses
Cefprozil (Cefzil)	PO	15–30 mg ÷ into 2 doses	Inappropriate
Ceftibuten (Cedax)	PO	9 mg once daily	Inappropriate
Cefuroxime (Kefurox, Zinacef)	IV, IM	Inappropriate	100–150 mg ÷ into 3 or 4 doses
Cefuroxime axetil (Ceftin)	PO	20–30 mg ÷ into 2 doses	Inappropriate
Cefdinir (Omnicef)	PO	14 mg ÷ into 1 or 2 doses	Inappropriate
Cefditoren (Spectracef)	PO	200–400 mg twice daily ^{b,d}	Inappropriate
Cefixime (Suprax)	PO	8 mg ÷ into 1 or 2 doses	Inappropriate
Cefotaxime (Claforan)	IV, IM	Inappropriate	100–180 mg ÷ into 4 to 6 doses
Cefpodoxime proxetil (Vantin)	PO	10 mg ÷ into 2 doses	Inappropriate
Ceftazidime (Fortaz, Tazicef)	IV, IM	Inappropriate	100–150 mg ÷ into 3 doses
Ceftriaxone (Rocephin)	IV, IM	Inappropriate	50–100 mg ÷ into 1 or 2 doses
Cefepime (Maxipime)	IV, IM	Inappropriate	100–150 mg ÷ into 2 or 3 doses
Carbapenems			
Ertapenem (Invanz)	IV, IM	Inappropriate	30 mg ÷ into 2 doses
Imipenem-cilastatin (Primaxin)	IV, IM	Inappropriate	60–100 mg ÷ into 4 doses
Meropenem (Merrem)	IV	Inappropriate	60–120 mg ÷ into 3 doses
Macrolides			
Azithromycin (Zithromax)	PO	10 mg on day 1, then 5 mg thereafter; 12 mg for pharyngitis	Inappropriate
Clarithromycin (Biaxin)	PO	15 mg ÷ into 2 doses	Inappropriate
Erythromycin base (numerous)	PO	30–50 mg ÷ into 4 doses	Inappropriate
Erythromycin ethylsuccinate (E.E.S., EryPed, Erythro)	PO	30–50 mg ÷ into 4 doses	Inappropriate
Erythromycin lactobionate (Erythrocin)	IV	Inappropriate	20–50 mg ÷ into 4 doses
Erythromycin stearate (numerous)	PO	30–50 mg ÷ into 4 doses	Inappropriate

Continued

TABLE 236.4 Daily Dosage Schedules for Antimicrobial Agents in Pediatric Patients Beyond Newborn Period—cont'd

Agent, Generic (Trade Name)	Route	Mild-to-Moderate Infections ^a	Severe Infections ^a
Lincosamides			
Clindamycin (Cleocin)	IV, IM	Inappropriate	20–40 mg ÷ into 3 or 4 doses
	PO	8–20 mg ÷ into 3 or 4 doses	Inappropriate
Vancomycin (Vancocin)	IV	Inappropriate	40–60 mg ÷ into 4 doses
Aminoglycosides			
Amikacin (Amikin)	IV, IM	Inappropriate	15–22.5 mg ÷ into 3 doses
Gentamicin (Garamycin)	IV, IM	Inappropriate	5–7.5 mg ÷ into 3 doses ^b
Kanamycin	IV, IM	Inappropriate	15–30 mg ÷ into 3 doses
Paromomycin	PO	25–35 mg ÷ into 3 doses	Inappropriate
Streptomycin	IM	Inappropriate	20–40 mg ÷ into 1 or 2 doses
Tobramycin (Nebcin)	IV, IM	Inappropriate	6–7.5 mg ÷ into 3 to 4 doses
Tetracyclines			
Doxycycline (numerous)	PO	2.2–4.4 mg ÷ into 1 or 2 doses	Inappropriate
Tetracycline	PO	25–50 mg ÷ into 4 doses	Inappropriate
Chloramphenicol	IV	Inappropriate	50–100 mg ÷ into 4 doses
Sulfonamides			
Erythromycin ethylsuccinate, sulfisoxazole (Pediazole, Eryzole)	PO	50 mg erythromycin/150 mg sulfa ÷ into four doses	Inappropriate
Sulfadiazine	PO	100–150 mg ÷ into 4 doses	Inappropriate
Trimethoprim-sulfamethoxazole (Bactrim, Septra, Sulfatrim, Cotrim)	PO	8–12 mg trimethoprim/40–60 mg sulfamethoxazole ÷ into 2 doses	Inappropriate
	IV	Inappropriate	10–20 mg trimethoprim/50–100 mg sulfamethoxazole ÷ into 4 doses
Fluoroquinolones			
Ciprofloxacin (Cipro)	PO	20–30 mg ÷ into 2 doses	Inappropriate
	IV	Inappropriate	20–30 mg ÷ into 2 doses
Rifampin (Rifadin)	PO	10–20 mg ÷ into 1 or 2 doses	20 mg ÷ into 2 doses
	IV	Inappropriate	20 mg ÷ into 2 doses
Metronidazole (Flagyl)	PO	15–50 mg ÷ into 3 or 4 doses	Inappropriate
	IV	Inappropriate	30 mg ÷ into 4 doses
Linezolid (Zyvox)	PO	Inappropriate	20–30 mg ÷ into 2 or 3 doses
	IV	Inappropriate	20–30 mg ÷ into 2 or 3 doses
Quinupristin-dalfopristin (Synercid)	IV	Inappropriate	22.5 mg ÷ 3 doses
Colistimethate sodium (Colistin, ColyMycin M)	IV, IM	Inappropriate	2.5–5 mg ÷ into 2 to 4 doses

IM, Intramuscularly; IV, intravenously; PO, orally.

^aTotal daily dosage (per kilogram). For larger children, maximal dosages may apply.

^bTotal dose.

^cNo longer available in the United States.

^dNot approved for children younger than 12 years of age.

^eA dose of 4 mg/kg once daily is used commonly in neonates. A dose of 67.5 mg/kg once daily in older children is investigational.

advisable to have the hospital laboratory determine serum antimicrobial concentrations. When this is not possible, careful follow-up is mandatory, and measurements of inflammatory indices, such as the erythrocyte sedimentation rate and C-reactive protein, are very useful in determining resolution of the infection.

Oral therapy can be considered for patients with osteomyelitis and suppurative arthritis only after an initial period of parenteral therapy, after results are available from cultures and susceptibility tests, and after the patient shows definite signs of resolution of inflammation. Oral therapy should be initiated before discharge from the hospital to ascertain compliance, determine serum antimicrobial concentrations when available, and observe for significant side effects that would preclude use of the oral antibiotic.

Food Interference With the Absorption of Some Oral Antibiotics

The absorption of some oral antimicrobial agents is decreased significantly when the drug is taken with food or near mealtime. These drugs include unbuffered penicillin G, penicillinase-resistant penicillins (i.e., nafcillin, oxacillin, cloxacillin, and dicloxacillin), ampicillin, and lincomycin. Dairy products and other foods or medications containing calcium

or magnesium salts interfere with the absorption of tetracyclines. Absorption of penicillin V, buffered penicillin G, amoxicillin, cephalixin, cefaclor, chloramphenicol, erythromycin, and clindamycin is affected only slightly by food. When absorption is affected by the concurrent ingestion of food, antibiotics should be taken 1 or more hours before or 2 or more hours after meals. A dosage schedule of four times daily, rarely used for common infections, can be arranged for the drug to be given on arising, 1 hour before lunch and supper, and at bedtime. Most orally administered antibiotics can be administered twice or three times daily, a schedule that is accommodated easily by most parents.

Intravenous Versus Intramuscular Administration

Although a brief period occurs when the serum antimicrobial concentration is higher after intravenous administration of an antimicrobial agent than after intramuscular administration, no therapeutic advantage of intravenous as opposed to intramuscular administration has been demonstrated. Intravenous administration should be used if the patient is in shock or is suffering from a bleeding diathesis. When prolonged parenteral therapy is anticipated, the pain of injection and the small muscle mass of infants and young children preclude the intramuscular route and render intravenous therapy preferable. The physician must

TABLE 236.5 Dosage Schedules for Antimicrobial Agents Used in Neonates

Antibiotic	Route	DOSAGE (mg/kg) AND INTERVAL OF ADMINISTRATION				
		WEIGHT <1200 g	WEIGHT 1200–2000 g		WEIGHT >2000 g	
		Age 0–4 wk	Age 0–7 Days	Age >7 Days	Age 0–7 Days	Age >7 Days
Penicillin G, crystalline (U)	IV	25,000–50,000 q12h	25,000–50,000 q12h	25,000–50,000 q8h	25,000–50,000 q8h	25,000–50,000 q6h
Penicillin G, procaine (U)	IM		50,000 q24h	50,000 q24h	50,000 q24h	50,000 q24h
Penicillin G, benzathine (U)	IM		50,000 once	50,000 once	50,000 once	50,000 once
Penicillinase-Resistant Penicillins						
Oxacillin	IV, IM	25 q12h	25–50 q12h	25–50 q8h	25–50 q8h	25–50 q6h
Nafcillin	IV, IM	25 q12h	25–50 q12h	25–50 q8h	25–50 q8h	25–50 q6h
Broad-Spectrum Penicillins						
Ampicillin IV, IM						
Meningitis		50 q12h	50 q12h	50 q8h	50 q8h	50 q6h
Other infections		25 q12h	25 q12h	25 q8h	25 q8h	25 q6h
Meropenem	IV	20 q12h	20 q12h	20 q12h	20 q12h	20 q12h or q8h
Cephalosporins						
Cefazolin	IV, IM	20 q12h	20 q12h	20 q12h	20 q12h	20 q8h
Cefotaxime	IV, IM	50 q12h	50 q12h	50 q8h	50 q12h	50 q6h or q8h
Ceftriaxone	IV, IM	50 q24h	50 q24h	50 q24h	50 q24h	75 q24h
Ceftazidime	IV, IM	30 q12h	30 q12h	30 q12h	30 q12h	30 q12h
Cefepime	IV, IM	30 q12h	30 q12h	30 q12h	30 q12h	30 q12h to 50 q8h
Clindamycin	IV, IM	5 q12h	5 q12h	5 q8h	5 q8h	5 q6h
Erythromycin	PO	10 q12h	10 q12h	10 q8h	10 q12h	10 q6h or q8h

IM, Intramuscularly; IV, intravenously; PO, orally.

Modified from Sáez-Llorens X, McCracken GH, Jr. Clinical pharmacology of antibacterial agents. In: Remington JS, Klein JO, editors. *Infectious Diseases of the Fetus and Newborn Infant*. 4th ed. Philadelphia: WB Saunders; 1995:1325.

TABLE 236.6 Dosage Schedule for Antibiotics Based on Postconceptional Age^a

Antibiotic	Route	DOSAGE (mg/kg) AND INTERVAL OF ADMINISTRATION: GESTATIONAL AGE PLUS WEEKS OF LIFE			
		≤26	27–34	35–41	≥42
Amikacin	IV, IM	7.5 q24h	7.5 q18h	7.5 q12h	7.5 q8h
Gentamicin	IV, IM	2.5 q24h	2.5 q18h	2.5 q12h ^b	2.5 q8h ^b
Tobramycin	IV, IM	2.5 q24h	2.5 q18h	2.5 q12h	2.5 q8h
Vancomycin	IV	10–15 q24h	10–15 q18h ^c	10–15 q12h ^c	10–15 q8h ^c or q6h

IM, Intramuscularly; IV, intravenously.

^aDosages should be adjusted according to serum drug concentrations.

^bSingle daily dosing is used commonly in neonates: 3–3.5 mg/kg (<35 wk) or 4 mg/kg (≥35 wk).

^cAt 28 days of life, vancomycin is administered at 20 mg/kg per dose; the interval remains the same.

be alert for thrombophlebitis, which can result from prolonged intravenous administration, and for sterile abscesses, which can develop after intramuscular administration.

Chloramphenicol, erythromycin, linezolid, tetracyclines, and vancomycin should be administered intravenously rather than intramuscularly. Chloramphenicol was thought to be absorbed poorly from intramuscular sites, although additional data suggested that such is not the case. Intramuscular injection of parenteral tetracyclines and erythromycin causes local irritation and pain, and intramuscular injection of vancomycin causes tissue necrosis. Care should be given to the administration of intramuscular injections.^{31,221} Sites that minimize the risk for local neural, vascular, or tissue injury should be selected. The preferred site varies with the age of the child: the upper anterolateral aspect of the thigh in infants, the ventrogluteal area in children older than 2 years of age, and the deltoid area for older children. Inadvertent intra-arterial injection of benzathine penicillin G can cause tissue damage.

“Push” Versus “Steady” or “Continuous Drip” Intravenous Administration

Antimicrobial agents can be administered intravenously by the “push” method, in which case the drug is infused in 5 to 15 minutes; by “steady

drip” in 1 to 2 hours; or by “continuous drip,” whereby the drug is given throughout the period of administration. The push method results in high antibacterial activity in serum for short periods, whereas the steady and continuous drip methods produce lower but more sustained activity. The risk for development of adverse effects influences whether an antimicrobial agent should be administered by push or by steady drip. Pharmacodynamic studies suggest optimization of bactericidal activity when aminoglycosides are given by push once daily because the activity of these agents is concentration dependent. By contrast, β -lactams are given preferably in several doses or by a continuous drip to maintain concentrations of drug at the infection site that exceed the MIC of the pathogen for 50% or longer of the dosing interval (time-dependent pharmacodynamic principle). Rapid administration (<5 minutes) of large intravenous doses of penicillin should be avoided because of possible adverse CNS effects. Aminoglycosides given by the intravenous route should be infused in 20 to 60 minutes to obtain optimal peak concentrations. Antimicrobial activity, especially for penicillins, can deteriorate if drugs are kept in solution at room temperature for prolonged periods, as may occur with use of the continuous drip method. Fresh solutions of penicillins should be administered every 6 to 8 hours when the continuous drip method is used.

Diffusion of Antimicrobial Agents Across Biologic Membranes

Diffusion of any drug across a biologic membrane depends on the molecular size of the drug, the degree of protein binding (only the unbound portion of the drug crosses), the degree of ionization at physiologic pH (only the unionized portion is available for equilibration), and solubility in lipids. Thus, the lipid solubility of the unionized and unbound fraction of an antimicrobial agent determines the capability of the drug to diffuse to the site of infection. Antibiotics usually are not distributed evenly throughout the body.^{263,264}

Diffusion of antimicrobial agents from blood into a joint space, pleural and pericardial fluid, and middle ear fluid is relatively unimpeded, and high concentrations of many drugs are achieved in these sites after systemic administration. More than 60% of the peak serum concentration of various penicillins and cephalosporins is present in the inflamed joint space.²⁶⁰ Loculations of fluid in the presence of fibrous adhesions may limit the passage of antimicrobial agents into infected areas.

Diffusion of antibiotics from blood into CSF or into the aqueous humor of the eye is limited. Drugs that are highly soluble in lipids, un-ionized, and minimally bound to proteins (e.g., chloramphenicol, isoniazid, rifampin, and sulfonamides) pass into CSF in high concentrations, even in the absence of inflammation, whereas drugs such as the macrolides diffuse into CSF little, if at all. Fluoroquinolones pass readily into the CSF space but do not have an indication for use for meningitis in children. Penicillins, cephalosporins, and aminoglycosides pass more effectively into CSF when the membrane is inflamed; variable, but often low, concentrations of drug in CSF can be present even in the early stages of meningitis. The β -lactams are pumped actively out of the CSF space by the choroid plexus, a process that is inhibited partially by inflammation.

Duration of Therapy

Physicians must rely on empirically derived schedules of therapy for rapid and complete resolution of disease and minimal risk in terms of clinical or microbiologic failure or drug toxicity. Numerous studies evaluating the duration of therapy have been performed for streptococcal pharyngitis. The results are consistent in suggesting that the following are appropriate: 10 days of oral therapy with penicillins, cephalosporins, or macrolides; 5 days of azithromycin; or a single intramuscular dose of benzathine penicillin G. Opinions vary and data are conflicting regarding the duration of treatment for diseases such as osteomyelitis, suppurative arthritis, and infections of the urinary tract. Radetsky²⁸⁶ wrote an enlightening history of the recommendations for the duration of treatment in bacterial meningitis and pointed out: "Even in the absence of specific data certain numbers have an unaccountable power to satisfy and reassure. 7, 10, 14 and 21 days have consistently appeared. Even in the trials performed at the dawn of the antimicrobial era, these numbers were chosen."

Dosage Schedules in Children With Renal or Hepatic Insufficiency

The kidneys are the major organs of excretion for most antimicrobial agents, including penicillins, cephalosporins, aminoglycosides, and tetracyclines (with the exception of doxycycline). Because impaired excretion can result in high and possibly toxic serum and tissue antimicrobial concentrations, alterations in dosage schedules should be considered in children with diminished renal function. Antibiotics that require careful dosage adjustment for renal impairment include aminoglycosides, ciprofloxacin, imipenem-cilastatin, meropenem, piperacillin/tazobactam, tetracyclines, TMP-SMX, and vancomycin. Agents requiring dosage adjustments only when renal failure is severe include most penicillins, cephalosporins, and clindamycin. Drugs that are eliminated by nonrenal mechanisms and therefore do not require adjustment of the dosage schedule for renal impairment include chloramphenicol, cloxacillin, dicloxacillin, doxycycline, erythromycin (including the newer macrolides), metronidazole, linezolid, nafcillin, oxacillin, and rifampin.³⁶²

Dosage schedules for patients with renal insufficiency can be altered by administering the usual dosage for the initial dose and increasing the interval between doses or decreasing individual doses (or both, in the case of renal shutdown). Although numerous guidelines have been

developed to assist the physician, these formulas have been generated from studies of adults with renal impairment, and pediatricians must be cautious in adapting the formulas for use in infants and young children.³⁶² Serum antimicrobial concentrations should be monitored when aminoglycosides, vancomycin, and other drugs with potential toxicity are administered to children with renal insufficiency. Hepatic disorders can alter plasma protein binding, tissue binding, hepatic metabolism, and the distribution of antimicrobials that are metabolized or excreted by the liver.³⁵⁶ Few data exist regarding adjustment of dosage schedules for antibiotics that are metabolized by the liver in patients with hepatic insufficiency.²⁰⁵ It would be prudent to avoid the use of tetracyclines and to exercise caution when prescribing chloramphenicol, clindamycin, metronidazole, macrolides, rifampin, and penicillinase-resistant penicillins to patients with underlying hepatic disease.

Topical Use of Antimicrobial Agents

Topical antimicrobial agents are used for a variety of indications: bacitracin or polymyxin ointments are available (in many cases without prescription) for first aid of minor cuts, abrasions, and burns; tetracycline, erythromycin, and clindamycin have been used for the treatment of pustular acne; and metronidazole is approved for the topical treatment of inflammatory lesions and erythema associated with rosacea. Erythromycin, chloramphenicol, sulfonamide, gentamicin, tobramycin, tetracycline, and a combination of TMP and polymyxin B ointment or drops are used for the treatment of conjunctivitis, styes, and other minor infections of the eye. Silver nitrate drops or erythromycin or tetracycline ointment is used for the prevention of gonococcal ophthalmia in newborn infants. A controlled trial involving newborn infants in Africa demonstrated equivalent or superior efficacy of a 2.5% ophthalmic solution of povidone-iodine in contrast to topical silver nitrate or erythromycin for prophylaxis against ophthalmia neonatorum caused by *C. trachomatis*, *N. gonorrhoeae*, staphylococci, or gram-negative bacteria.¹⁶⁴ Ofloxacin drops (Floxin Otic) are approved for the treatment of otitis externa, chronic suppurative otitis media, and acute otitis media in children with tympanostomy tubes.³⁸ Ciprofloxacin and dexamethasone otic solution (Ciprodex) is approved for children 6 months of age and older who have tympanostomy tubes, to treat acute otitis media caused by *S. aureus*, *S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, and *P. aeruginosa*, as well as acute otitis externa caused by *S. aureus* and *P. aeruginosa*. Mupirocin is effective in vitro against most *S. aureus* (including methicillin-resistant strains) and group A streptococci and is approved for the treatment of impetigo. At present, approximately 10% of CAMRSA strains are resistant to mupirocin; in some areas, the rate is as high as 30%. Mupirocin applied to the anterior nares may be of value in eradicating nasal carriage of methicillin-resistant staphylococci. However, the few well-designed controlled studies that exist do not support the routine use of mupirocin, except possibly for patients undergoing dialysis, because prolonged use of mupirocin has been associated with resistance to this agent, and recolonization is a common occurrence.⁷⁷ Most antibiotics used topically, such as bacitracin, neomycin, and polymyxin B, are of limited use as systemic agents. Retapamulin ointment (Altabax), a pleuromutilin antibacterial, was approved by the FDA in 2007 for topical treatment of impetigo caused by *S. aureus* (methicillin-susceptible isolates only) or *S. pyogenes* in patients aged 9 months or older. The dosage is twice-daily applications for 5 days.

Absorption after application to the conjunctivae or large areas of denuded skin can be significant, but application to normal skin does not result in detectable concentrations of antimicrobial activity in blood or urine. Sensitization does not appear to be an important problem with most topical antibiotics, although some patients with chronic dermatoses may react to certain agents such as neomycin. Antimicrobial agents of value for systemic use should not be applied extensively to the surface of the body or used routinely in closed units (e.g., burn units) because of the risk for inducing resistance.

The Committee on Drugs of the American Academy of Pediatrics concluded that topical antimicrobial agents may prevent infection after minor cuts, abrasions, and burns, but in most instances, gentle cleansing of minor wounds and burns is sufficient antiseptics.⁸ Systemic antibiotics, rather than topical drugs, are recommended for chronic pyoderma, including impetigo, especially when more than several lesions are present.

Intermittent administration of inhaled tobramycin (twice daily for 4 weeks followed by 4 drug-free weeks) is indicated for the management of children and adults with cystic fibrosis and *P. aeruginosa* infection. Clinical data from a large, randomized, placebo-controlled trial indicate that tobramycin treatment improves pulmonary function, decreases the density of *P. aeruginosa* in sputum, reduces the risk for hospitalization, and is well tolerated. The diminished microbial reduction during the third cycle of treatment was not explained by the development of resistance to tobramycin.²⁹⁰

The use of antimicrobial-coated central venous catheters is not accepted practice in pediatrics, but limited evidence supports its potential usefulness, particularly if rates of catheter-related bloodstream infections exceed 3.3/1000 catheter days and if standard protective procedures already have been implemented.²⁶⁹ Rates of bacterial colonization and bloodstream infections associated with the use of central venous catheters in high-risk adult patients were found to be lower in patients whose catheters were impregnated with minocycline and rifampin than in those impregnated with chlorhexidine and silver sulfadiazine.⁹⁵

Current Use of Antimicrobial Agents for Prophylaxis

Chemoprophylaxis refers to the use of drugs to prevent infection. Antimicrobial treatment refers to the use of drugs after infection has taken place or when early signs of infectious disease are present or infection is suspected. The use of antimicrobial agents for prophylaxis has proved to be of value in many circumstances (Table 236.7) and currently is considered to be of probable value or is investigational for the prevention of infections in many other situations. Prophylaxis is of greatest value when the following criteria are met: use of a single drug with a narrow spectrum of activity, use of a drug with limited side effects or toxicity, and prevention of colonization by an organism of known susceptibility and one that is unlikely to become resistant during the period of drug use. Current recommendations from the American Academy of Pediatrics include the following circumstances: (1) site-related infections: otitis media, urinary tract infection, and endocarditis; (2) exposed host: *B. pertussis* exposure, *N. meningitidis* exposure, traveler's diarrhea, perinatal group B streptococci exposure, bite wound (i.e., human, animal, or reptile), infants born to HIV-infected mothers, close exposure to influenza in unimmunized hosts, susceptible contacts of index cases of invasive *H. influenzae* type b disease, and exposure to aerosolized spores of *B. anthracis*; (3) vulnerable host

(pathogen): oncology or immunosuppressed patients (with *P. jirovecii* or fungi), organ transplant patients (with cytomegalovirus, *P. jirovecii*, or fungi), HIV-infected children (with *P. jirovecii* or polysaccharide encapsulated bacteria), preterm neonates (with *Candida* sp.), patients with anatomic or functional asplenia (with polysaccharide-encapsulated bacteria), chronic granulomatous disease (with *S. aureus* and certain other catalase-positive bacteria and fungi), congenital immunodeficiencies (with various pathogens), rheumatic fever (with group A streptococci), and neonatal herpes simplex virus disease.¹²

Use of Antimicrobial Agents for Children in School or Group Daycare

Infants and children usually return to their school or daycare during a course of antimicrobial therapy. Because of problems with the administration of drugs outside the home, physicians should prescribe medications that are given infrequently, are relatively stable at ambient temperatures, and need only simple directions. Drugs that are administered in once- or twice-daily schedules are preferred. Chewable tablets, when available, may be of value in reducing the need for the school or daycare provider to measure specific amounts of liquid suspension and to refrigerate suspensions. Single-dose regimens, such as intramuscular benzathine penicillin G for group A streptococcal infections, may be advantageous. Guidelines for administration of medications in schools have been published by the Council on School Health of the American Academy of Pediatrics and should be useful to the physician for prescribing drugs to children who attend school.¹⁰

Restriction on Use of Antimicrobial Agents for Infants and Children

Many antimicrobial agents are approved for use in adults but have not been approved by the FDA for use in infants and children. The reasons for lack of approval are drugs with insufficient experience in children, such as tigecycline (Tygacil); agents with real or suspected toxicity in children (e.g., damage to articular cartilage in juvenile animals associated with administration of the fluoroquinolones) that should be used only when necessary; and antibiotics for which the manufacturers have chosen not to submit data on use in children to the FDA, such as metronidazole (Flagyl) and cefotetan (Cefotan). These agents appear to be safe and effective in infants and children as a result of use by pediatricians, but no well-controlled studies of their efficacy or safety in this age group

TABLE 236.7 Antimicrobial Prophylaxis in Children

Prevention of Infection in Certain Patients	Antimicrobial Agent
Group A streptococcal infection in patients with a history of rheumatic fever	Benzathine penicillin G IM, penicillin V PO
Bacterial endocarditis in patients at risk during surgical procedures:	
• Dental procedures, surgery on the upper respiratory tract	Amoxicillin PO; clindamycin, cephalexin, cefadroxil, azithromycin, or clarithromycin in penicillin-allergic patients
• Gastrointestinal tract surgery or instrumentation	Cefazolin
• Esophageal, gastroduodenal (high-risk)	Cefazolin
• Biliary tract	Cefoxitin or metronidazole plus gentamicin <i>or</i> Cefazolin plus metronidazole <i>or</i> Clindamycin plus gentamicin or ciprofloxacin
• Colorectal, appendectomy (uncomplicated)	
• Genitourinary tract surgery or instrumentation	Amoxicillin PO, ampicillin IV, ampicillin plus gentamicin, cefazolin, or vancomycin plus gentamicin (for penicillin-allergic patients)
Neonatal sepsis caused by group B streptococcus	Penicillin (preferred) or ampicillin IM or IV (intrapartum)
Gonococcal ophthalmia in newborn infants	Silver nitrate or erythromycin ophthalmic ointment
Meningococcal disease in contacts	Rifampin, ceftriaxone
<i>Haemophilus influenzae</i> type b disease in contacts	Rifampin
Recurrent episodes of acute otitis media	Amoxicillin, sulfisoxazole
Postoperative infections	Penicillinase-resistant penicillins or first- or second-generation cephalosporins
Tuberculosis infections in close contacts	Isoniazid
Recurrent urinary tract infections	Trimethoprim-sulfamethoxazole, nitrofurantoin
Sepsis in patients with functional asplenia	Penicillin, amoxicillin, trimethoprim-sulfamethoxazole

IM, Intramuscularly; IV, intravenously; PO, orally.

have been performed. Although a drug that has been approved for adults may be used in children at the discretion of the physician, the prudent physician chooses to use such a drug only when it is uniquely appropriate for the infectious illness and records the basis for choice of the unapproved drug.

Home Intravenous Antibiotic Therapy

Home intravenous antibiotic therapy is now available in most communities and permits discharge from the hospital earlier than in the past. The safety, effectiveness, and cost-efficiency of such a program have been proved, and these factors are of particular value for children who require 3 to 6 weeks of therapy for severe osteomyelitis or suppurative arthritis or who have chronic disease that can be managed in the home, such as cystic fibrosis or malignant disease. In many cases, home care enables the patient to resume normal activities, including return to school. The following are factors that are necessary before consideration of home care:

1. Availability of a team that includes the physician, the pharmacist, a vendor who will supply the drug and supplies, and an intravenous specialty nurse
2. A disease that is stable and requires only continued antimicrobial therapy
3. Unavailability of a suitable oral antibacterial agent (see the earlier discussion on [use of oral preparations for serious infections](#)) and availability of a stable parenteral antibiotic with low toxicity that the patient can tolerate (as demonstrated in the hospital) and preferably with a long half-life to allow infrequent dosing
4. A member of the household who is able to administer the antibiotic and provide aseptic care of the venous access device
5. Appropriate follow-up that can be maintained for monitoring safety and effectiveness

If problems with venous access arise and ceftriaxone is appropriate therapy, the drug can be administered successfully in the outpatient setting by the intramuscular route once daily by a nurse.^{129,302}

Drug-Drug Interactions

Drug-drug interactions can lead to therapeutic failure because of lack of effective activity of one or both drugs or serious adverse events resulting from toxic serum concentrations of one or both drugs.¹³⁰ Most children do not require daily medications for chronic diseases; thus, drug-drug interactions occur less commonly in pediatric than in geriatric patients, but the potential for interactions exists and must be considered when prescribing antibiotics. Because drug-drug interactions are not limited to prescription medications, inquiry into the use of over-the-counter medications should be made. Mechanisms for drug-drug interactions are classified as follows: physiochemical, in which one drug is physically incompatible in solution with another; pharmacokinetic, whereby one drug interferes with the absorption, distribution, metabolism, or excretion of the other; and pharmacodynamic, whereby one drug affects the activity of a second drug. Examples of each mechanism include inactivation of aminoglycosides by extended-spectrum penicillins, decreased absorption of tetracyclines with coadministration of antacids, antagonism of sulfonamide activity by procaine as a result of competition for PABA binding sites, and interference with the CYP450 oxidase enzyme system as observed with rifampin and macrolide drugs or with the azole antifungal agents and cyclosporine.

SUMMARY AND CONCLUSIONS

A summary of the information contained in this chapter is presented in the following questions that the physician must consider for appropriate use of antimicrobial agents in children:

1. Before the drug is administered:
 - a. Have appropriate cultures been obtained for a specific microbiologic diagnosis?
 - b. Has the patient received this drug or related compounds previously? If so, did the patient tolerate the drug? Were there any signs of toxicity or sensitization?
 - c. Does the patient have a condition that requires exclusion of some drugs? For example, children with glucose-6-phosphate

dehydrogenase deficiency may have induced hemolysis when a sulfonamide, nitrofurantoin, or primaquine is administered.

2. Factors to be considered when writing orders for the administration of antimicrobial agents in a hospital:
 - a. If the drug is given by mouth, will coadministration with food interfere with absorption, or is diarrhea a risk?
 - b. If a parenteral route is used, should the drug be administered by the intravenous or the intramuscular route?
 - c. If the drug is administered by the intravenous route, is push, steady drip, or continuous drip preferred?
 - d. Should the drug be instilled directly at the site of infection?
 - e. Will the drug diffuse to the site of infection?
 - f. Should incision and drainage of the infected area be performed before or after beginning therapy? Incision and drainage should be considered whenever a significant collection of pus is present. If a drainage procedure is performed, material should be obtained for culture and susceptibility testing.
 - g. Does the patient have renal or hepatic insufficiency that requires alteration of the dosage schedule?
 - h. Are any special precautions required for household contacts? Prophylaxis may be warranted in special circumstances of infection occurring in the household, daycare center, or nursery school.
3. Use of antimicrobial agents in children who are treated as outpatients:
 - a. Have the names and functions of the drugs been communicated to the patient and the parent? Do any of the drugs prescribed interact with each other?
 - b. Is the dosage schedule simple and satisfactory for the family circumstances (e.g., the child's school schedule or the schedule of the working parents)?
 - c. Does the child have an adequate supply of the drug until it can be purchased? If not, the use of starter packages is of value. Administration of the first dose in the clinic is advantageous because it provides knowledge of acceptance and tolerability of the drug by the child.
 - d. Are parents given instructions for reporting the clinical course by telephone? Is an appointment made for the next visit?
 - e. Does the patient or parent know how to assess adequacy of response to the drug? Does the parent know how to take the child's temperature?
 - f. Is the total amount of drug prescribed adequate for the course? Will refills of the prescription be needed?
 - g. Is the drug provided in a convenient dosage form? Will the package be provided with an adequate means of measuring the drug? Does the agent require refrigeration?
 - h. Has the patient or parent been informed of signs of side effects or toxicity?
 - i. Are generic equivalents of the drug adequate?
 - j. Will the patient be able to pay for the drug if it is purchased elsewhere (away from the clinic)? If applicable, will a third party pay for this prescription? (In some states, prescriptions by brand name may not be filled because reimbursement by the third-party payer, such as Medicaid, is insufficient.)
4. After the patient's course:
 - a. How long should the patient take the drug?
 - b. When should the initial choice of antimicrobial agents be reconsidered? When the results of cultures and appropriate susceptibility tests are available, should the initial choice be reevaluated and altered, if necessary?
 - c. What studies should be performed to monitor the safety and adequacy of the regimen? Hematologic indices must be measured during the administration of certain antibiotics to detect any adverse reaction. Vigilance is important to detect symptoms or signs attributable to adverse reactions.
 - d. Are repeat cultures necessary? In certain cases, the most appropriate criterion of efficacy is evaluation of the results of cultures.
 - e. What clinical and laboratory signs of efficacy should be monitored? Signs may differ for different diseases and various drugs but should be considered by the physician when the course of therapy is designed.

BOX 236.2 Factors Contributing to Antimicrobial Failure

Host Related

Foreign body present
Anatomic defect
Defect in immune response to infection
Poor absorption of enteral antibiotic

Disease Related

Antibiotic inappropriate for the disease
Ancillary therapy not instituted (e.g., surgical drainage)
Sequestered focus of infection (undetected or inaccessible)

Organism Related

Acquired resistance to an antimicrobial agent
Superinfection with resistant bacteria

Drug Related

Inadequate adherence
Improper dosage schedule: route, dose, or duration
Inadequate diffusion to the site of infection
Drug-drug interactions: antibiotic inactivation or antagonism
Deterioration of drug during storage

5. What factors should be considered if the patient fails to respond to the antimicrobial agent? If the patient does not respond appropriately to the course of therapy, various factors must be considered, including those related to the disease, host, drug, or organism (Box 236.2).
6. What steps can be taken to prevent reinfection? For example, in certain circumstances prophylactic antibiotics, immunizations, or surgical procedures may be warranted.

Acknowledgements

We thank George H. McCracken Jr and colleagues for their contributions to this chapter in previous editions.

Antimicrobial prophylaxis is the limited administration of an antimicrobial agent or agents before or immediately after exposure to an infectious agent, with the intent of preventing an infection. Prevention is always preferred, provided the means are available and the risk-benefit and cost-benefit ratios are acceptable. The focus of this chapter is on prevention of morbidity and mortality from bacterial infections through prophylactic, and often empirical, use of antimicrobial agents. For many prophylactic regimens, employment is justified by severity of the disease; and in many instances, an evidence base supporting their use is meager or nonexistent. For other regimens, such as those employed in surgery, substantial evidence of efficacy exists for many recommended regimens. Prophylaxis against viral infections such as human immunodeficiency virus and varicella will not be discussed but rather only prophylaxis against bacterial infections and some fungal (yeast) infections. For discussions of available prophylaxis against viral infections, consult chapters addressing specific viral agents.

GENERAL PRINCIPLES OF PROPHYLAXIS

Factors influencing efficacy of prophylactic regimens are related to the potential pathogen, the prophylactic agent, the host, and the disease to be prevented (Box 237.1). In addition, the pharmacology, pharmacodynamics, and pharmacokinetics of antimicrobial agents will affect the efficacy of prophylaxis and dictate dosage and timing of administrations of antibiotics and duration of use. Failure to consider these factors will often lead to ineffective prophylaxis, overuse of antimicrobial agents, promotion of resistant microorganisms, economic waste, and risk for development of toxicity or other significant side effects.

Bacterial Pathogen

Prophylaxis is likely more effective when a single pathogen is targeted. In general, the greater the number of targeted pathogens, the less effective, more toxic, and more expensive the regimen becomes. Ideally, prophylaxis should be administered at the time of exposure to the potential pathogen. If exposure is prolonged or continuous, prophylaxis becomes less effective and less desirable. Bacteria that are not endogenous to the host (i.e., not part of the host's normal flora) generally are targeted more effectively if the exposure is known and identified.

Disease

The severity of the disease to be prevented is a major consideration. Potentially fatal infections such as meningococcemia, infections that result in high morbidity such as endocarditis, and infections of surgically implanted devices are justifiably targeted. Prophylaxis usually is not required for minor illnesses (e.g., cuts, abrasions). The site of infection also is important. Adequate concentrations of antimicrobial agents are achieved readily in organs that are highly vascular and have no anatomic barriers, whereas infections in restricted anatomic compartments (e.g., middle ear) or those that involve prosthetic materials may require special consideration.

Antimicrobial Agent

The most desirable prophylactic regimen is one in which a single, inexpensive antimicrobial drug is used with a narrow spectrum, which is easily administered and well tolerated with minimal side effects. The less frequently an agent is given, the more reliable the compliance of the patient to the prophylactic regimen.⁸⁰ When prophylaxis can be achieved effectively with a single administration of an antimicrobial agent, prophylaxis is likely to approach the ideal.

PROPHYLAXIS IN NEONATES

Ophthalmia Neonatorum

Prophylaxis recommendations target *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Ideally, prophylaxis should be directed at infants who are exposed to these two pathogens, but routine mass identification of such groups with certainty is problematic. Although routine prophylaxis has been discontinued in some countries (United Kingdom, Sweden),⁴⁰ topical antibiotic prophylaxis for ophthalmia neonatorum for these two agents continues to be recommended in the United States.¹⁶⁰

In the past, topical 1% silver nitrate solutions, available in single-dose ampules, were the standard prophylaxis, and tetracycline ophthalmic preparations were considered the alternative. Neither tetracycline nor silver nitrate is produced in the United States; instead single-dose tubes of an ophthalmic ointment containing 0.5% erythromycin are provided. All three agents are effective prophylaxis for gonococcal ophthalmia neonatorum.⁷² However, because silver nitrate frequently causes chemical conjunctivitis, its use has been largely discontinued in most countries. Gentamicin ophthalmic ointment is associated with severe ocular reactions in neonates and should not be used for prophylaxis.¹¹² Erythromycin and tetracycline ophthalmic ointments appear to be as effective as silver nitrate solution for routine prophylaxis of gonococcal ophthalmia,^{93,162} but silver nitrate probably is the most reliably effective agent against penicillinase-producing *N. gonorrhoeae*. If erythromycin ointment is not available because of antimicrobial shortages, ceftriaxone (25–50 mg/kg intravenously [IV] or intramuscularly [IM], not to exceed 125 mg in a single dose) may be used.¹⁶⁰

The effectiveness of erythromycin or tetracycline in the prevention of ophthalmia caused by penicillinase-producing *N. gonorrhoeae* has not been established. No topical regimen has proven efficacy against *Chlamydia conjunctivitis* or prevention of invasive *Chlamydia* infections of the neonate, such as lower respiratory tract infection.^{26,41,73} Furthermore, topical regimens do not eliminate *C. trachomatis* from the nasopharynx and do not prevent pneumonia. Therefore mothers identified with chlamydial colonization or infection are provided with effective treatment, as noted later.

Prophylaxis should be administered as soon as possible after birth. Each eyelid should be wiped gently with sterile cotton before local prophylaxis is administered. Care must be exercised to ensure that the solution or ointment is in the conjunctival sac and that it is not flushed from the eye after instillation. Administration of ophthalmic prophylaxis is law in most states. Most important, maternal treatment against *Chlamydia trachomatis* or gonorrhea infection should be provided if these infections are identified in pregnant women before delivery during routine screening. Infants born to mothers with active gonococcal infections at birth should receive a single dose of ceftriaxone (25–50 mg/kg IM, not to exceed 125 mg). Antimicrobial regimens for treatment of sexually transmitted infections of both infants and mothers are reviewed in the periodic updates of the Centers for Disease Control and Prevention (CDC) sexually transmitted infection treatment guidelines.¹⁶⁰

Group B Streptococcal Infections

Prophylaxis is recommended for the prevention of early-onset (onset within the first week of life) neonatal group B streptococcal infections.^{7,13,27,115,128,133} No recommendations for prophylaxis against late-onset infections exist. The current indications for treatment of neonates and maternal carriers or those mothers at risk for transmission of group B streptococcal infections to their infants is reviewed in Chapter 83 and available from the CDC³⁹ and the American Academy of Pediatrics (AAP).⁷

BOX 237.1 Factors Influencing Effective Prophylaxis

- Single versus multiple potential pathogens
- Time of exposure to the pathogen
- Source of pathogens
- Severity of the disease to be prevented
- Targeted organs that could become infected
- Spectrum of activity of the antimicrobial agent
- Pharmacokinetics and the pharmacodynamics of the selected agent
- Duration of chemoprophylaxis
- Cost, toxicity, side effects, and acceptability of the agent
- Likelihood and consequences of emerging resistance

Multiple regimens have been evaluated to reduce vertical transmission of group B streptococcus.² The antepartum use of oral antimicrobial agents to eradicate group B streptococcus colonization of mothers (antepartum chemoprophylaxis) has not been successful, even when sexual partners were treated concurrently.¹¹⁵ Prophylaxis of neonates with penicillin G or ampicillin soon after birth (postnatal chemoprophylaxis) is ineffective in preventing early-onset group B streptococcal disease, primarily because in most patients infection occurs in utero and the infants do not have symptoms at or within a few hours after birth.

Therefore current recommendations focus on treatment of all colonized women identified by recommended universal testing.^{7,39} The AAP and CDC recommend that lower vaginal and anorectal (single-swab) specimens for culture be obtained at 35 to 37 weeks' gestation, placed into selective broth medium, transported, and subcultured onto solid media.^{13,39} Both hybridization assays and DNA amplification techniques for detection of group B streptococci also are available and serve as the only acceptable alternatives to culture.^{23,79} Rapid nucleic amplification methods are available for testing women at the time of entry into labor and thus provide opportunities for treatment of women who may not have been tested at 35 to 37 weeks' gestation. Maternal group B streptococcus carriers identified antepartum or those without culture or identification at the time of delivery with rapid testing but with one or more risk factors (see Chapter 83) should be given intrapartum intravenous ampicillin (2 g initially, then 1 g every 4 hours) or penicillin G (5 million U initially, then 2.5–3 million U every 4 hours until delivery).³⁹ Penicillin-allergic women may be given clindamycin or erythromycin intravenously. Previous delivery of an infant with invasive group B streptococcal disease warrants intrapartum maternal chemoprophylaxis for each subsequent pregnancy, regardless of maternal colonization.

Intrapartum antibiotic prophylaxis prevents substantial numbers of cases of early-onset neonatal group B streptococcal infection⁸¹ and decreases the incidence of maternal group B streptococcal postpartum complications, including endometritis.^{96,107} Since the institution of intrapartum antimicrobial prophylaxis, the rate of invasive group B streptococcal disease has declined by greater than 65% in prescreened mothers, and administration of intravenous ampicillin reduces the risk for development of early-onset group B streptococcal infection by 36% in infants born to women with premature rupture of membranes.²² However, the decrease in the rate of group B streptococcal disease may be associated with an increased rate of disease caused by gram-negative pathogens.

Necrotizing Enterocolitis

Neonatal necrotizing enterocolitis (NEC) is a multifactorial disease, with bowel wall necrosis of variable length and depth being the characteristic common feature. Factors including ischemic stress, disruption of the bowel mucosal barrier, and resultant bacterial proliferation and invasion of the intestinal wall are part of the pathogenesis of NEC. Therefore suppression of gastrointestinal flora with nonabsorbable oral antimicrobial agents has been used in an effort to prevent the development of NEC in premature infants. Administration of oral kanamycin or gentamicin prophylactically in the first few hours of life has resulted

in contradictory data. Furthermore, selective overgrowth of resistant organisms in the bowel and significant systemic absorption of aminoglycosides from injured mucosa are potential risk factors. Therefore, currently, oral aminoglycosides are not recommended for the routine prophylaxis or treatment of NEC. One report¹¹³ suggests that oral vancomycin given for 48 hours before introduction of oral feeding may be beneficial in preventing NEC. These observations on use of antibiotics for prevention of NEC have not been confirmed, and such prophylaxis is not recommended. Lastly, orally administered probiotics have been suggested to alter the bowel flora and to reduce the incidence or severity of NEC. A 2014 Cochrane review on the use of probiotics to prevent the development of NEC included 24 randomized controlled trials with just more than 5000 infants.¹ These studies were marked by extreme variability in inclusion criteria and the dosing and content of the probiotic supplements. In neonates younger than 37 weeks estimated gestational age (EGA) or with birth weight of less than 2500 g, NEC incidence was reduced by 57%, with a 35% reduction in mortality with the use of enteral probiotics. No cases of probiotic-associated bacteremia were reported. A 2015 Cochrane review assessing lactoferrin alone for the prevention of NEC included two randomized controlled trials with just more than 500 premature infants.¹²⁰ A 70% reduction in the incidence of NEC and mortality was documented (5% risk difference; number needed to treat of 20). Bacteremia in two premature neonates (26 2/7 weeks and 28 6/7 weeks EGA) receiving enteral probiotics has been reported with the use of *Bifidobacterium longum*, with DNA sequencing documenting identical strains to those contained in the probiotic capsules used.²⁵

Intravascular Catheter Insertion

Infection with coagulase-negative staphylococci, primarily *Staphylococcus epidermidis*, is likely to occur in premature infants or infants who have indwelling vascular catheters. Low-grade sepsis is the most common clinical manifestation; however, meningitis, endocarditis, omphalitis, cellulitis, and other focal infections may occur. Two randomized trials of low-dose vancomycin added to total parenteral nutrition (TPN) fluids (25 µg of vancomycin per milliliter of fluid) suggested that such a prophylactic regimen significantly reduces coagulase-negative staphylococcal infections in small premature infants in neonatal intensive care units (NICUs).^{85,144} Despite the possible effectiveness of vancomycin prophylaxis,²⁰ the AAP has not made a routine recommendation for low-dose vancomycin because of the potential promotion of emerging resistance in gram-positive pathogens.

Continuous administration of fluconazole has been studied in high-risk, low-birth-weight infants who are at risk for development of systemic infections caused by *Candida* spp. Currently, the AAP Committee on Infectious Diseases recommends fluconazole prophylaxis for extremely low-birth-weight infants in NICUs with moderate (5–10%) or high (>10%) rates of invasive candidiasis.⁵ The recommended regimen for extremely low-birth-weight infants is to initiate fluconazole treatment intravenously during the first 48 to 72 hours after birth at a dose of 3 mg/kg and administer it twice a week for 4 to 6 weeks, or until intravenous access is no longer required for care. Oral absorption of fluconazole is very good in neonates who are feeding. This regimen has been recommended because it has not been associated with emergence of resistance.

Recent interest in anti-infective agents such as ethanol as a lock solution for treatment or elimination of colonization of chronic indwelling lines has been proposed as an acceptable alternative to antibiotics.^{118,129,138}; however, although these agents have been effective for treatment or elimination of potential pathogens in biofilms infecting lines, they remain only recommended for treatment of lines infected with organisms not responsive to recommended treatment.¹¹⁶ A Cochrane review of antimicrobial lock prophylaxis in adults and children did demonstrate a moderate benefit in the prevention of gram-positive catheter-related sepsis, although with an unforeseeable impact on the development of resistance.¹⁵³ Several small studies (<30 patients each) have demonstrated a reduction in the rate of central line-associated bloodstream infections (CLABSIs) with the use of ethanol lock prophylaxis in children with TPN-dependent intestinal failure.^{16,117,124,155} A randomized controlled trial of 307 pediatric oncology patients younger

than 18 years demonstrated a significant reduction in CLABSI with the use of ethanol locks, with a number needed to treat of 13. No serious adverse events were reported.¹³²

DISEASE-TARGETED PROPHYLAXIS

Rheumatic Fever

Group A streptococcal infection of the pharynx is the precipitating cause of rheumatic fever. Appropriate antibiotic treatment of streptococcal pharyngitis prevents development of acute rheumatic fever in most cases.⁵¹ Because at least one-third of episodes of acute rheumatic fever result from inapparent streptococcal infections⁴⁴ and some patients with symptoms do not seek medical care, not all instances of rheumatic fever are preventable. Prevention of first attack (primary prevention) is accomplished by proper identification, adequate antibiotic treatment, and eradication of streptococcal infection. An individual who has suffered an attack of rheumatic fever is at very high risk for recurrence after subsequent group A streptococcal pharyngitis and needs continuous chemoprophylaxis to prevent such recurrence (secondary prevention).⁴⁶ The prophylaxis of rheumatic fever also is discussed in Chapter 29.

Primary Prevention

Primary treatment of episodic recurrent group A streptococcal infections is important in the prevention of rheumatic fever and recurrent episodes. The diagnosis and treatment of group A streptococcal infections are discussed in Chapter 82, and the prevention of rheumatic fever and its prophylaxis are discussed in Chapter 29. Acceptable regimens for treatment of acute group A streptococcal infections are provided in Table 237.1.^{6,17,67,157} In addition, once-daily dosing of amoxicillin (50 mg/kg per day to a maximum of 1 g per day) is now recommended as a means of primary prevention of acute rheumatic fever in addition to twice-daily dosed penicillin.^{6,14,140}

Even when treatment is started as long as 9 days after the onset of acute illness, penicillin may effectively prevent primary attacks of rheumatic fever.³⁷ Therefore a brief delay (24–48 hours) for processing of the throat culture before initiation of antibiotic therapy does not increase the risk for development of rheumatic fever. However, therapy also shortens the duration of clinical symptoms, so initiation of therapy at the earliest possible time is favored.²¹ Intramuscular benzathine penicillin G is preferred to oral penicillin, particularly for patients who are unlikely to complete a 10-day course of oral therapy and for patients with a personal or family history of rheumatic fever, rheumatic heart

disease, or other factors that place them at substantial risk for development of rheumatic fever.⁴⁶

Secondary Prevention

Continuous antibiotic administration is indicated in patients at risk for developing recurrent disease after having infection with group A streptococcus or for those children with congenital or acquired cardiac disease who are at risk for development of endocarditis. Both the AAP and the American College of Cardiology provide recommendations for prophylaxis.

An individual in whom streptococcal pharyngitis develops after a previous attack of rheumatic fever is at high risk for having a recurrent attack of rheumatic fever, even after asymptomatic infections or symptomatic infections that are treated optimally. Therefore prevention of recurrent rheumatic fever requires continuous antimicrobial prophylaxis rather than recognition and treatment of acute episodes of streptococcal pharyngitis.⁴⁶ Continuous prophylaxis is recommended for patients with a well-documented history of rheumatic fever (including cases manifested solely by Sydenham chorea) and for those with definite evidence of rheumatic heart disease. Such prophylaxis should be initiated as soon as acute rheumatic fever or rheumatic heart disease is diagnosed. A full therapeutic course of penicillin or other effective regimen should be given first to patients with acute rheumatic fever to eradicate residual group A streptococcus, even if a throat culture is negative at that time. Streptococcal infections occurring in family members of patients with rheumatic fever should be treated promptly.

An injection of 1.2 million units of benzathine penicillin G for patients weighing more than 27 kg (600,000 units for those weighing <27 kg) every 4 weeks is the recommended regimen for secondary prevention in most circumstances in the United States (see Table 237.1). In countries where the incidence of rheumatic fever is particularly high, in special circumstances, or in certain high-risk individuals, such as patients with residual rheumatic carditis, administration of benzathine penicillin G every 3 weeks is justified and recommended.^{99,100} Long-acting penicillin is of particular value in patients with a high risk for having a recurrence of rheumatic fever, especially those with rheumatic heart disease, in whom recurrence is very serious. The advantages of giving benzathine penicillin G must be weighed against the inconvenience to the patient and the pain of injection, which causes some individuals to discontinue prophylaxis.

Successful oral prophylaxis (penicillin V or sulfadiazine; see Table 237.1) depends primarily on the patient's adherence to prescribed

TABLE 237.1 Prevention of Rheumatic Fever

Agent	Dose	Mode	Duration
Primary Prevention			
Benzathine penicillin G	600,000 units for patients ≤27 kg (60 lb) 1.2 million units for patients >27 kg (60 lb)	Intramuscularly	Once
Penicillin V	Children: 250 mg 2–3 times daily (<27 kg [60 lb]) Children ≥27 kg (60 lb) or adults: 500 mg 2–3 times daily	Orally	10 days
Amoxicillin	50 mg/kg/day once daily (maximum dose: 1 g)	Orally	10 days
For Individuals Allergic to Penicillin			
Erythromycin (azithromycin for 5 days may be substituted; see package insert for dosage) ^a	40 mg/kg/day divided 2–4 times daily (1 g maximum/day)	Orally	10 days
Secondary Prevention			
Benzathine penicillin G	1.2 million units (>27 kg) or 600,000 units (<27 kg) every 3–4 wk or	Intramuscularly	See text
Penicillin V	250 mg twice daily or	Orally	See text
Sulfadiazine	0.5 g once daily for patients ≤27 kg (60 lb) 1 g once daily for patients >27 kg (60 lb)	Orally	See text
For Individuals Allergic to Penicillin and Sulfadiazine			
Erythromycin	250 mg twice daily	Orally	See text

^aClarithromycin for 10 days or azithromycin for 5 days in recommended doses is also effective.

Modified from Dajani A, Taubert K, Ferrieri P, et al. Treatment of acute streptococcal pharyngitis and prevention of rheumatic fever: A statement for health professionals. *Pediatrics*. 1995;96:758-764.

regimens.⁴⁵ Patients need to be given careful and repeated instructions about the importance of prophylaxis. Most failures of prophylaxis occur in nonadherent patients. Even with optimal adherence of the patient, the risk for having a recurrence is higher in individuals receiving oral prophylaxis than in those receiving intramuscular benzathine penicillin G.⁶⁰ Oral agents are more appropriate for patients at lower risk for having rheumatic recurrence. Accordingly, some physicians elect to switch therapy to oral prophylaxis when patients have reached late adolescence or young adulthood and have remained free of rheumatic attacks for at least 5 years.

Duration of appropriate prophylaxis has been defined for those with rheumatic fever without carditis for 5 years after the last episode or until 21 years of age, whichever is longer, whereas for those with carditis, prophylaxis should be at least 10 years or until age 21 years, whichever is longer.^{6,24} For those with residual heart disease (e.g., persistent valvular disease), prophylaxis should be given at least 10 years after the last episode or until age 40 years, whichever is longer.^{6,67}

Although sulfonamides are not effective in the eradication of group A streptococcus, they do prevent development of infection. Sulfonamide prophylaxis is contraindicated in late pregnancy because of transplacental passage of such drugs and potential competition with bilirubin for albumin-binding sites.

For patients who are allergic to penicillin and sulfisoxazole, erythromycin or another macrolide (e.g., azithromycin or clarithromycin) is recommended. No data have been published about the use of other penicillins, macrolides, or cephalosporins for the secondary prevention of rheumatic fever, but the AAP has stated that clarithromycin for 10 days or azithromycin for 5 days is adequate for treatment.⁶

Bacterial Endocarditis

In 2007,¹⁵⁷ and again in 2008,¹⁵⁸ recommendations for antimicrobial prophylaxis were changed significantly from 1997 guidelines.⁴⁷ The rationale for these changes included three central concepts. First, endocarditis is much more likely to result from frequent exposure to random bacteremias associated with daily activities than from bacteremia caused by a dental, gastrointestinal tract, or genitourinary procedure. Second, prophylaxis may prevent an exceedingly small number of cases of endocarditis (if any) in individuals who undergo any procedure, and the risk for adverse reactions to antibiotics probably exceeds the benefit in any form of prophylactic treatment. Third, maintenance of optimal oral health and hygiene may reduce the incidence of bacteremia from daily activities and is more important than prophylactic antibiotics for a dental procedure to reduce the risk for endocarditis.

Therefore recommendations for the use of antibiotic prophylaxis after 2007 were limited to the highest risk cardiac conditions. Cardiac conditions associated with the highest risk are listed in [Box 237.2](#). Prophylaxis is no longer provided to all subjects who have the highest

lifetime risk for endocarditis. For patients with high-risk conditions listed in [Box 237.2](#), all dental procedures that involve manipulation of gingival tissues or the periapical region of teeth or perforation of the oral mucosa are reasonable for administration of dental prophylaxis. Events and procedures such as routine anesthetic injections through noninfected tissues, taking dental radiographs, placement or removal of prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth, and bleeding from trauma to the lips or oral mucosa do not require prophylaxis. The recommendations for regimens for oral and parenteral antibiotics listed in [Table 237.2](#) are for all dental procedures for which dental prophylaxis is reasonable for persons with high-risk conditions.

Recommendations for antimicrobial prophylaxis for respiratory procedures are only for procedures that involve the incision or incisional biopsy of the respiratory mucosa, such as tonsillectomy and adenoidectomy. Therefore prophylaxis is not recommended for bronchoscopy unless an incision of the respiratory tract will be made. An antimicrobial regimen that includes coverage of viridans group streptococci³² can be selected from [Table 237.2](#).

When using prophylaxis for high-risk procedures of the gastrointestinal or genitourinary tract, possible involvement of enterococcal organisms must be considered, as well as the inclusion of mixed infections with aerobic and anaerobic gram-negative and gram-positive organisms.^{22,56} However, only enterococci are frequent causes of endocarditis. In the revised recommendations of 2007, the administration of prophylactic

BOX 237.2 Cardiac Conditions Associated With the Highest Risk for Adverse Outcomes From Endocarditis for Which Prophylaxis With Dental Procedures Is Reasonable

- Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
- A history of previous infectious endocarditis
- Congenital heart disease (CHD)
 - Unrepaired cyanotic CHD, including palliative shunts and conduits
 - Completely repaired congenital heart defect with prosthetic material or device inserted by surgery or catheter intervention during the first 6 months after the procedure
 - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop valvulopathy

TABLE 237.2 Prophylactic Antimicrobial Regimens for Dental Procedures

Situation	Agent	REGIMEN, SINGLE DOSE 30–60 MINUTES BEFORE PROCEDURE	
		Adults	Children
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medications	Ampicillin or Cefazolin or ceftriaxone	2 g IV or IM 1 g IV or IM	50 mg/kg IV or IM 50 mg/kg IV or IM
Allergic to penicillins or ampicillin—oral	Cephalexin or Clindamycin or Azithromycin or clarithromycin	2 g 600 mg 500 mg	50 mg/kg 20 mg/kg 15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medications	Cefazolin or ceftriaxone or Clindamycin	1 g IV or IM 600 mg IV or IM	50 mg/kg IV or IM 20 mg/kg IV or IM

IM, Intramuscularly; IV, intravenously.

Modified from Wilson W, Taubert K, Gewitz M, et al. Prevention of infective endocarditis. Guidelines from the American Heart Association. *Circulation*. 2007;116(15):1736-1754.

antibiotics solely to prevent endocarditis is not recommended for patients who undergo esophagogastroduodenoscopy or colonoscopy, which is in contrast to previous recommendations made in 1997. For patients with infections of the gastrointestinal or genitourinary tract who may have intermittent or sustained enterococcal bacteremia or for those who receive antibiotic therapy to prevent wound infection or sepsis associated with a gastrointestinal or genitourinary tract procedure, it is reasonable to include an agent active against enterococci, such as penicillin, ampicillin, piperacillin, or vancomycin. Similarly, for patients with high-risk conditions listed in [Box 237.2](#), antibiotic therapy to eradicate the infection from the urine before surgery is reasonable for those who are scheduled for an elective cystoscopy or other urinary tract manipulation or those who have an enterococcal urinary tract infection or colonization. Amoxicillin or ampicillin is the preferred agent for enterococci, but vancomycin may be used in those intolerant of β -lactam antibiotics.

Incision of surgically scrubbed skin without an underlying or adjacent infection is not likely to cause bacteremia, and prophylaxis is not recommended. In contrast, procedures on infected skin, skin structure, or musculoskeletal tissues are likely to cause endocarditis. Therefore, for children with high-risk cardiac conditions, a therapeutic regimen administered for treatment of the infection should contain an agent active against staphylococci and β -hemolytic streptococci, such as an antistaphylococcal penicillin or cephalosporin. Vancomycin or clindamycin may be administered to children unable to tolerate β -lactam antibiotics or those who are known or suspected to be infected with a methicillin-resistant strain of *Staphylococcus aureus* (MRSA).

The 2007 changes in recommendations for prophylaxis for endocarditis represent substantial changes to all the recommendations before 1997. Therefore a summary of those recommendations is listed in [Box 237.3](#). In addition, the recommendations to withhold prophylaxis to subjects with a number of conditions have not changed, and those

conditions or situations are listed in [Box 237.4](#). A retrospective analysis of cases of infective endocarditis in children younger than 18 years at 37 medical centers 4 years before and 3 years after the 2007 release of the new endocarditis guidelines for antimicrobial prophylaxis failed to document any increase in infective endocarditis (1157 cases identified; 1.6% difference in cases before and after guideline release, $P = .7$).¹²²

Recurrent Otitis Media

Acute otitis media is one of the most common infections in infants and children and has a tendency to recur, particularly during the first few years of life. In addition to tympanostomy tube placement and adenoidectomy, antimicrobial prophylaxis is one of the options that may be considered for the management of recurrent otitis media.^{36,55,127} Chemoprophylaxis of otitis media is discussed also in Chapter 16.

Updated guidelines from 2013 on the management of acute otitis media in children published by the AAP, however, do not recommend antibiotics for prophylaxis in children with a history of recurrent acute otitis media.⁹⁸

Patients most likely to benefit from prophylaxis include those younger than 2 years, those in out-of-home child care, and Native American children.^{89,121} Prophylaxis is directed against the most common potential pathogens that cause otitis media: *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and nontypeable *Haemophilus influenzae*. Amoxicillin, at a

BOX 237.3 Summary of Changes and New Recommendations for Antibiotic Prophylaxis for Bacterial Endocarditis^a

- Bacteremia resulting from daily activities is much more likely to cause endocarditis than bacteremia associated with a dental procedure.
- Only an extremely small number of cases of endocarditis might be prevented by antibiotic prophylaxis even if prophylaxis were 100% effective.
- Prophylaxis is now recommended only for high-risk procedures, and prophylaxis is no longer recommended for any other form of congenital heart disease except for those listed in [Box 237.2](#).
- Prophylaxis is reasonable only for dental procedures that involve the manipulation of the gingival tissues or periapical region of the teeth or perforation of the oral mucosa, and only for those with very high-risk conditions.
- Antibiotic prophylaxis is reasonable for procedures on the respiratory tract, infected skin or skin structures, or musculoskeletal tissues only for patients with underlying cardiac conditions with the highest risk for adverse outcomes from endocarditis.
- Antibiotic prophylaxis solely to prevent endocarditis is no longer recommended for genitourinary or gastrointestinal tract procedures.
- Conditions previously listed as not requiring prophylaxis (1997) continue to not require prophylaxis and now include vaginal delivery, hysterectomy, and tattooing, although body piercing for patients with high-risk conditions for endocarditis should not be performed.

^aData from Wilson W, Taubert KA, Gewitz PB, et al. Prevention of infective endocarditis: Guidelines from the American Heart Association. A guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *Circulation*. 2007;116:1736-1754.

BOX 237.4 Conditions for Which Antibiotics Should Not Be Used Solely for Endocarditis Prophylaxis

Cardiac Conditions

- Isolated secundum atrial septal defects
- Surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus (without residual and beyond 6 months of age)
- Previous coronary artery bypass graft surgery
- Mitral valve prolapse without valvular regurgitation
- Physiologic, functional, or innocent heart murmurs
- Previous Kawasaki disease without valvular dysfunction
- Previous rheumatic fever with valvular dysfunction
- Cardiac pacemakers (intravascular and epicardial and implanted defibrillators)

Respiratory Tract

- Endotracheal intubation
- Bronchoscopy with a flexible bronchoscope, with or without biopsy
- Tympanostomy tube insertion

Gastrointestinal Tract

- Endoscopy with or without gastrointestinal biopsy

Genitourinary Tract

- Vaginal hysterectomy
- Vaginal delivery
- Cesarean section
- In uninfected tissue:
 - Urethral catheterization
 - Uterine dilation and curettage
 - Therapeutic abortion
 - Sterilization procedures
 - Insertion or removal of intrauterine devices

Other

- Cardiac catheterization, including balloon angioplasty
- Implanted cardiac pacemakers, implanted defibrillators, and coronary stents
- Incision or biopsy of surgically scrubbed skin
- Circumcision

dose of 20 mg/kg, or sulfisoxazole, at a dose of 50 mg/kg, may be given orally each evening for a period of 3 to 6 months or during the winter months. Although many other antimicrobial agents are used for the treatment of otitis media, only amoxicillin and sulfisoxazole currently are considered as prophylactic agents because only these two agents have undergone critical analysis in prospective trials. Antimicrobial prophylaxis must be used with great caution and balanced against the potential for increasing the emergence of resistant organisms, particularly *S. pneumoniae*, and the possible occurrence of drug-associated toxicity (e.g., neutropenia, rash, or other). Other measures that may decrease the incidence of recurrent acute otitis media include eliminating smoking in the home, reducing group child care attendance, eliminating pacifiers, and administering influenza and the pneumococcal conjugate vaccines. If these measures do not prevent recurrent infections, referral to an otolaryngologist is recommended for evaluation and possible tympanostomy tube placement or adenoidectomy, or both procedures.

Recurrent Urinary Tract Infection

Urinary tract infection (UTI) occurs in approximately 5% of girls and 1% to 2% of boys.¹⁶⁵ Recurrent UTIs are noted in 30% to 50% of children with UTIs, with most recurrences taking place within 3 months after the initial episode. Eighty percent of recurrences are new infections caused by different colonic bacterial species that have become resistant to recently administered antibiotics. The recurrence rate is not altered by extending the duration of treatment.

Renal parenchymal infections and renal scarring are well-recognized complications of UTIs in children.^{78,105,139} Parenchymal scarring is found in 10% to 15% of children with UTIs,^{143,165} hypertension will develop in an estimated 10% of children with this complication, and renal insufficiency may develop in a smaller number.⁸³ Vesicoureteral reflux is noted in 30% to 50% of children with UTIs,¹⁰⁵ the frequency being related directly to the number of UTI episodes and inversely to age. Children with reflux have a much higher incidence (30–60%) of pyelonephritic scarring than do children without reflux. More than 90% of children with renal parenchymal scarring have had vesicoureteral reflux and a history of UTI.^{143,165}

Children who have three or more UTIs in a 12-month period may benefit from suppressive antibiotic therapy for as long as 6 months to allow repair of intrinsic bladder defense mechanisms.¹⁶⁵ In children with anatomic defects or reflux, suppressive therapy may be needed for as long as the underlying defect exists.

Appropriate prophylactic agents should result in low serum but high urinary levels of the medication, have minimal effect on fecal flora, be well tolerated, and be inexpensive.¹⁰⁴ Methenamine mandelate (75 mg/kg divided every 12 hours, maximum dose 500 mg) is a suitable agent for prophylaxis because it releases formaldehyde in an acid medium. A pH of 5.5 or lower must be maintained in the urine to obtain optimal results. Ascorbic acid or other acidifying agents should be used to achieve the desired urine acidity. Other useful agents for prophylaxis in children with normal renal function are trimethoprim-sulfamethoxazole (TMP-SMX), nitrofurantoin, and nalidixic acid.^{30,59,74,105,137} TMP-SMX can be given at 2 mg of TMP and 10 mg of SMX per kilogram in a single daily dose or at 5 mg of TMP and 25 mg of SMX per kilogram twice a week. TMP has the additional unique characteristic of diffusing into vaginal and urethral fluids, thereby decreasing bacterial colonization with members of the Enterobacteriaceae family and diminishing ascending reinfection.^{74,145} Nitrofurantoin is recommended at 1 to 2 mg/kg (maximum dose, 100 mg/day), taken each night. It has been used effectively as prophylaxis for recurrent UTIs in infants and children. Pulmonary, neurologic, and hepatic adverse effects have been reported but are rare occurrences.¹⁰⁵ Nalidixic acid (not recommended for children younger than 3 months) is administered at 30 mg/kg divided every 12 hours. It is a bactericidal agent for most of the common gram-negative uropathogens. More recently, various cephalosporins and amoxicillin-clavulanic acid have been used as prophylactic agents with good results.¹⁰⁴ Prophylactic agents are best administered as a single dose at bedtime. Despite the previous studies suggesting efficacy of UTI antimicrobial prophylaxis, it remains controversial and largely unsupported by well-performed studies. In the largest randomized controlled trial conducted on antimicrobial prophylaxis for recurrent UTI in children, and the

only study adequately powered to detect a reduction in recurrent UTI with antimicrobial prophylaxis, 607 children (mean age, 12 months) with vesicoureteral reflux were randomly assigned to receive either TMP-SMX or placebo, with a primary outcome of preventing recurrent UTIs.¹⁵⁰ Prophylaxis reduced the risk for recurrent UTI by 50% (risk difference of 12%) compared with placebo. However, the study was not powered to assess for a reduction in renal scarring, and no difference between groups was seen in this study for this variable. The risk for a recurrent UTI with an *E. coli* strain resistant to TMP-SMX was threefold higher in the prophylaxis group (63% vs. 19%).

No studies of prophylaxis in children without nocturnal continence have shown efficacy, and prophylactic regimens employing broad-spectrum antibiotics (e.g., amoxicillin, cephalexin) are associated with the emergence of recurrent infections caused by antibiotic-resistant organisms such as *Pseudomonas aeruginosa*.

POSTEXPOSURE PROPHYLAXIS

Prophylaxis targeted against specific organisms after an individual is exposed is discussed in this section.

Pertussis

Prompt administration of erythromycin or other approved macrolide drugs to those in close contact with a case of pertussis is effective in limiting secondary transmission. Close contacts are household members, attendees of group child care facilities, and other individuals who are in contact with the index infected individual for 4 hours or more a day. Chemoprophylaxis is recommended irrespective of age or vaccination status because immunity after receiving pertussis immunization is not absolute and may not prevent development of infection.¹¹ The recommended dose of erythromycin is 40 to 50 mg/kg per day (maximum, 2 g/day) to be given orally in four divided doses for 14 days. Both clarithromycin (15 mg/kg, up to a maximum of 1 g, divided twice daily for 7 days) and azithromycin at standard doses (10 mg/kg the first day, up to a maximum of 500 mg, followed by 5 mg/kg, up to a maximum of 250 mg, each of the days 2 through 5) have been shown to be as effective as erythromycin and are much better tolerated.³⁸ Infants younger than 5 months should receive 10 mg/kg per dose once daily for 5 days. Individuals who are allergic to erythromycin or macrolides or those who cannot tolerate their side effects may be given TMP-SMX, although the efficacy of this regimen has not been documented. The dose is 8 mg/kg per day (TMP) and 40 mg/kg per day (SMX) orally in two divided doses for 14 days.³⁸

Persons who have been in contact with an infected individual should be monitored closely for respiratory symptoms for 2 weeks after the last contact. The risk for contracting pertussis in adults providing medical care to children should be recognized. Symptoms may be mild and not readily recognized as pertussis; however, such individuals can transmit the infection.

Meningococcal Infections

Close contacts of patients with invasive disease caused by *Neisseria meningitidis* (meningococcemia, meningitis, or both) are at higher risk for acquisition of infection than is the general population. Secondary cases and outbreaks may occur in households, group child care centers, nursery schools, colleges, and military camps.¹⁰ The attack rate for household contacts is 0.3% to 1% (300 to >1000 times the rate in the general population). Spread from patients to medical care providers occurs infrequently unless intimate contact (e.g., mouth-to-mouth resuscitation, intubation, suctioning) occurs. Respiratory tract cultures are not recommended and are not of value in deciding who should receive prophylaxis.¹⁰

If chemoprophylaxis is to be used it should be administered as soon as possible, preferably within 24 hours of identification of the index case.¹⁰ Treatment with penicillin G, ampicillin, or sulfonamides for meningococcal disease does not reliably eradicate nasopharyngeal carriage of *N. meningitidis*, whereas treatment with extended-spectrum cephalosporins (e.g., ceftriaxone and cefotaxime) does eliminate carriage. Therefore antimicrobial chemoprophylaxis should be administered to the index patient before discharge from the hospital if the patient has been treated with the first three antibiotics.

The antibiotic of choice in most instances is rifampin. The recommended regimen is 10 mg/kg (maximum, 600 mg) every 12 hours for a total of four doses in 2 days. A liquid preparation can be formulated, or the powder can be mixed with applesauce or a similar vehicle. The rifampin prophylaxis regimen recommended for *H. influenzae* type b disease (see later) also is effective for meningococcal prophylaxis. Rifampin prophylaxis has several shortcomings.^{109,134} It fails to eradicate *N. meningitidis* in 10% to 20% of pharyngeal carriers.¹⁰¹ It is not recommended for pregnant women. Side effects occur frequently and include headache, dizziness, gastrointestinal symptoms, discoloration of body secretions (saliva, tears, urine), staining of contact lenses, and hepatotoxicity. Finally, several studies have documented the emergence of resistant meningococcal strains after administration of rifampin prophylaxis.¹³⁴ Failure of rifampin prophylaxis in the contact of a case with rifampin-resistant invasive meningococcal disease has also been reported.⁴⁸

If the meningococcal isolate is known to be susceptible to sulfonamides, sulfisoxazole may be recommended, but currently it is difficult to provide susceptibility data for most laboratories. The dose is 500 mg/day for infants, 500 mg every 12 hours for children 1 to 12 years of age, and 1 g every 12 hours for children older than 12 years and adults. The duration of prophylaxis is 2 days.

During an outbreak, a single intramuscular injection of ceftriaxone was significantly more effective than rifampin in eradicating meningococci at 1 week (97% vs. 75%) and at 2 weeks (97% vs. 81%) after prophylaxis.¹³⁴ Ceftriaxone administered as a single intramuscular dose (125 mg for children younger than 15 years and 250 mg for adults) now is recommended as an acceptable alternative for prophylaxis. Ceftriaxone has the advantages of ease of administration, possibly greater efficacy, and safety in pregnancy. For high-risk contacts 18 years or older, a single 500-mg oral dose of ciprofloxacin is a third option for meningococcal prophylaxis.

Haemophilus influenzae Type b Infections

The risk for development of secondary invasive disease with *H. influenzae* type b is age dependent.¹⁹ The risk incidence of disease has declined dramatically with the routine use of *Haemophilus* conjugate vaccines. However, in the era when *H. influenzae* type b infections occurred frequently, household contacts younger than 1 year had the highest risk (6%) for acquisition of secondary illness; the risk in children 4 years or younger also was high (2.1%). Children older than 6 years and adults are at little or no risk. The risk for children attending group child care centers may be increased but appears to be less than that for household contacts.^{32,61,103,110,119} Exposed hospital personnel do not require antimicrobial prophylaxis. Data on the risk for spread with invasive disease due to *Haemophilus* serotypes other than b, such as type a or type f, are unknown, and currently prophylaxis is not recommended for serotypes other than type b.

In addition to protecting vaccinated children against invasive disease, conjugate vaccines appear to decrease pharyngeal colonization, which further reduces *H. influenzae* type b transmission to unvaccinated children. Prophylaxis currently is recommended for all household contacts, regardless of age, if at least one of the contacts is younger than 4 years and not immunized completely.⁸ Complete immunization is defined as having received a conjugate vaccine: (1) at least one dose at 15 months or older, (2) two doses between 12 and 14 months of age, or (3) two or more doses before 12 months of age with a booster at 12 months or older.

Prophylaxis for nursery and group child care center contacts is less well defined, and definitive recommendations are lacking. In general, prophylaxis is recommended for child care centers with the same regimen as that recommended for households if (1) the center is attended by unvaccinated or incompletely vaccinated children younger than 2 years where contact is 25 hours per week or more or (2) two or more cases of invasive *H. influenzae* type b disease occur among attendees within 60 days and unvaccinated, or incompletely vaccinated, children attend the facility.¹⁵¹ In facilities where all contacts are older than 2 years, prophylaxis need not be given, regardless of vaccination status.

Rifampin in a single dose of 20 mg/kg per day (maximum, 600 mg) for 4 days effectively eliminates oropharyngeal carriage of *H. influenzae* type b in 95% of treated individuals.⁸ This regimen has been shown to

be effective in preventing secondary cases of invasive *H. influenzae* type b disease in household members, group child care settings, and classroom contacts.^{19,32} Prophylaxis should be initiated as soon as possible because most secondary cases occur during the first week after identification of the index case.¹⁹ The index patient also should receive rifampin prophylaxis, usually initiated during hospitalization and just before discharge.

If prophylaxis is given to limit secondary spread to a cohort (household or group child care), children vaccinated with any *H. influenzae* type b vaccine and unvaccinated susceptible children should receive prophylaxis.⁸ Prophylaxis is not recommended for pregnant women.

Tuberculosis

The three goals of preventive therapy for tuberculosis are (1) to prevent asymptomatic (latent) infection from progressing to clinical (active) disease, (2) to prevent recurrence of past disease, and (3) to prevent initial infection after exposure to persons with active disease in individuals who have negative tuberculin skin test results. The first two goals are covered in detail elsewhere (see Chapter 96); prevention of initial infection after exposure is addressed here. Chemoprophylaxis is given in an attempt to prevent the establishment of infection, and the recipient is protected only as long as antituberculous therapy is continued.

In the United States, isoniazid administered for 9 months is the preferred drug for children for chemoprophylaxis against *Mycobacterium tuberculosis*, for susceptible children exposed to active tuberculosis, or for those with positive reactive skin tests or interferon- γ release assays (latent tuberculosis infection [LTBI]). The recommended daily dose of isoniazid is 10 to 15 mg/kg per day (maximum, 300 mg/day) to be given as a single dose. However, alternative regimens, including a 6-month regimen of daily or weekly isoniazid, may be considered for children who cannot comply with a 9-month regimen. For both the 9- and 6-month regimens, twice-weekly (each isoniazid dose 20–30 mg/kg, maximum 900 mg), directly observed therapy regimens are equal in efficacy to the daily regimens. On the basis of data from randomized controlled trials, the use of once-weekly rifapentine and isoniazid with directly observed therapy for 12 weeks is now an acceptable option for the treatment of LTBI in children 12 years and older.^{12,82,146} Adherence has been shown to be superior with this regime, with equivalent efficacy when compared with 9 months of isoniazid. Dosing is as follows: rifapentine: 10 to 14 kg—300 mg, 14.1 to 25 kg—450 mg, 25.1 to 32 kg—600 mg, 32.1 to 49.9 kg—750 mg, and 50 kg and over—900 mg; for isoniazid: 15 mg/kg, rounded to the nearest 50 or 100 mg; maximum of 900 mg.

Approximately 9% of isolates in the United States are resistant to isoniazid. However, most experts still recommend isoniazid to treat children with LTBI, unless there is contact with a person with known isoniazid-resistant tuberculosis. If the source case is found to be have an isoniazid-resistant, rifampin-susceptible organism, isoniazid should be discontinued and rifampin (10–20 mg/kg, 600 mg maximum) should be given for a total of 4 months.¹² For those exposed to multidrug-resistant tuberculosis strains (defined as resistance to isoniazid and rifampin), neither the ideal regimen nor duration is known; however, drugs to consider include pyrazinamide, fluoroquinolones, and ethambutol, depending on the susceptibility of the isolate, and individual consultation with a specialist in the treatment of tuberculosis is advisable.

Persons exposed to an infectious case of tuberculosis should undergo tuberculin skin testing or testing with a blood interferon- γ release assay, have a chest radiograph, and receive isoniazid prophylaxis or another appropriate and approved regimen as recommended earlier. If the tuberculin test result is negative, the chest radiograph is normal, and the individual is not anergic, isoniazid or another appropriate regimen should be administered for 12 weeks and contact with the index patient should be broken. Isoniazid may be discontinued if the result of a repeated skin test or interferon- γ release assay after 12 weeks of prophylaxis remains negative. If the skin test result becomes positive, isoniazid is continued for a total of 9 months. Candidates for postexposure prophylaxis include persons with impaired immunity; household contacts, particularly children younger than 4 years; recent contacts, especially human immunodeficiency virus–positive contacts; and persons known to be anergic from populations with a high prevalence of tuberculosis.

Management of a neonate whose mother or other household contact has tuberculosis should be based on individual considerations. In the case of an infant born to a mother (or where a household contact is present) when the chest radiograph is negative but the mother or contact has a positive tuberculin skin test or interferon- γ release assay, the mother and contact are candidates for treatment of latent tuberculosis infection, but the infant needs no special evaluation or therapy and can breast-feed. If the mother or a household contact has suspected or active tuberculosis disease, this infection should be reported to the health department and appropriate therapy should be started immediately. If the mother has active disease, the infant should be evaluated for congenital infection and should be separated from the mother or contact, or both, or until the mother or household contact is wearing a mask and receiving treatment. When the infant is receiving isoniazid prophylaxis, separation is no longer necessary. When the mother has received effective therapy, for at least 2 weeks, she may breast-feed the infant.¹²

HOST-TARGETED PROPHYLAXIS

Human and Animal Bites

Human and animal bites are relatively common occurrences. According to the CDC, more than 4.7 million animal bites occur annually in the United States and account for approximately 1% of all pediatric emergency visits.^{4,135,152} Dog bites account for 80% to 90% of animal bites that require medical care.³¹ The organisms most frequently isolated in human bites are *S. aureus*, γ -hemolytic streptococci, *Bacteroides* spp., *Eikenella corrodens*, and *Fusobacterium* spp.¹⁴⁷ In animal bites, *Pasteurella multocida*, *S. aureus*, and anaerobic cocci are the main pathogens.¹⁴⁸

Data on the use of prophylactic antimicrobial agents after bites are sparse, and the role of prophylaxis in patients who seek medical care early for bite wounds is uncertain.^{18,53,89,135,142} However, because these wounds usually are contaminated with potential pathogens, the administration of prophylaxis (or early treatment) should be considered for patients who have the following risk factors: moderate or severe bite wounds, especially with edema or crush injury; puncture wounds (common in cat bites), especially if there is penetration of bone, tendon sheath, or joints; a facial, hand or foot, or genital area bite; wounds in immunocompromised and asplenic children; or wounds with delayed presentation with signs of infection (e.g., delay of 18 hours or more between the time of injury and the time of initial physician assessment).^{18,31,52,102,135,166} For many of these indications, the use of antibiotics is in effect early treatment rather than prophylaxis because contamination of the wound occurs at the time of the bite. A Cochrane review identified eight randomized controlled trials of antimicrobial prophylaxis for the prevention of infection in animal bites. Significant benefit with the use of prophylaxis was demonstrated for human bites and in the three studies assessing hand bites (26% risk reduction for infection).^{75,106}

Because most human and animal bites result in polymicrobial aerobic and anaerobic infections, prophylaxis should target these organisms. For initial prophylaxis, amoxicillin-clavulanic acid (30–50 mg/kg per day) probably is optimal therapy.^{28,31,59,142} Prophylaxis is recommended for 3 to 5 days. For children with penicillin allergy, an extended-spectrum cephalosporin or TMP-SMX plus clindamycin has been recommended.⁴ Although they are only moderately active against *P. multocida*, macrolides, including erythromycin 30 to 50 mg/kg per day and standard doses of clarithromycin or azithromycin, are accepted alternatives in penicillin-allergic children, specifically when these organisms are isolated. Other experts recommend clindamycin 30 mg/kg per day divided into three doses as an alternative in children allergic to penicillins or cephalosporins, as noted previously.

Asplenia

The spleen constitutes approximately 25% of the lymphoid mass. It filters blood at a rate of 150 mL/minute and plays an important role in the primary defense against bacteria that gain circulatory access.¹⁴⁹ The spleen has an active role in phagocytosis, is a major source of T lymphocytes, and produces immunoglobulin M antibodies, complement, opsonins, and tuftsin (a phagocytosis-promoting tetrapeptide).

Asplenia may be congenital or acquired. In the past, splenectomy was performed frequently and for a variety of indications; however,

currently, a number of methods are available for splenic salvage after trauma. Overwhelming and often fatal septicemia and meningitis occur with increased frequency in asplenic individuals.¹⁶³ The frequency of sepsis is 60 times greater in children who undergo splenectomy or those with splenic dysfunction (e.g., sickle cell disease) than in normal children. The risk for sepsis or severe outcome from sepsis is greater in children who lose splenic function by disease or trauma before 2 years of age or in those who have congenital absence of the spleen. Numerous congenital cardiac conditions carry high risk for development of congenital asplenia. Fatality from sepsis in splenectomized individuals is 200 times more common than that in the normal population.¹⁴⁹ The risk for development of sepsis is greatest in patients who have undergone splenectomies for underlying immunologic or reticuloendothelial disorders, and the risk is lowest in children after splenectomy for trauma.⁹⁰ In all categories, risk is highest in young infants and children, but it extends to teenagers and adults as well. The period of heightened susceptibility to infection is the initial 1 to 2 years after splenectomy; however, fulminant infection has been reported as long as 25 years after splenectomy.

S. pneumoniae is the most common cause of septicemia in splenectomized individuals. Despite prompt diagnosis and treatment, pneumococcal septicemia is associated with a fatality rate as high as 50%. Overall, 80% of postsplenectomy infections are caused by bacteria with capsular polysaccharides, particularly *S. pneumoniae* and *H. influenzae*.^{141,149} Although *N. meningitidis* also has a polysaccharide capsule, lack of terminal components of complement constitute the greatest risk for development of infection, and whether the incidence of sepsis is higher in persons with asplenia is unclear. However, because overwhelming meningococcal sepsis has been reported in patients with asplenia, it is reasonable to include these patients as an at-risk population for this pathogen.

To reduce the likelihood of serious infections after splenectomy, several measures are advisable. Splenectomy should be performed only when it is absolutely indicated. If possible, the best approach is to delay the surgical intervention until the child is 5 or 6 years of age. For children with congenital high-risk conditions, the 13-valent pneumococcal polysaccharide protein conjugate vaccine should be provided in the recommended schedules. Although multivalent pneumococcal polysaccharide vaccine (PPS23) provides incomplete protection for patients undergoing splenectomy, especially infants and young children, it should be administered to all patients who are older than 2 years, ideally 2 weeks before splenectomy is performed and 8 weeks after any conjugate pneumococcal immunization.¹¹⁴ A booster dose of PPS23 is indicated 5 years after immunization, with no more than two total doses of PPS23 before the age of 65 years.¹¹⁴ Vaccination against *H. influenzae* type b and *N. meningitidis* types A, C, Y, and W-135 with the appropriate polysaccharide or polysaccharide-protein conjugate vaccine recommended for use in children should be provided. The 2015 CDC recommendations advise immunization of individuals with functional or anatomic asplenia with one of the two meningococcal B vaccines (a two-dose series of the MenB-4C or a three-dose series of the MenB-FHbp vaccines) (Table 237.3).⁶² The 2013 CDC recommendations advise immunization with a quadrivalent meningococcal vaccine in children with asplenia down to 2 months of age (MenACWY-CRM at 2, 4, 6, and 12 months of age or MenACWR-D at 9 and 12 months of age) (Table 237.4).¹⁰¹

In addition to pneumococcal and meningococcal immunization, asplenic children should be immunized with *H. influenzae* vaccines as recommended for normal children beginning at 2 months of age. Previously unimmunized asplenic children younger than 5 years of age should be given *Haemophilus* conjugate vaccines according to the CDC catch-up schedule.

Antibiotic prophylaxis is recommended for many children with asplenia regardless of their immunization status. For children with sickle cell anemia or congenital asplenia, antibiotic prophylaxis should be initiated as soon as the diagnosis is established, preferably before 2 months of age. Although other children with asplenia or splenic dysfunction, such as those with thalassemia or with malignant neoplasms, may be candidates for antibiotic prophylaxis, there is less consensus for children with splenectomy following trauma. The AAP Committee on Infectious Diseases recommends that in addition to immunization,

TABLE 237.3 Recommendations for Meningococcal B Immunization for Children With Asplenia

Meningococcal Serogroup B	AGE AT SPLENECTOMY (ADMINISTER ONE VACCINE PRODUCT BELOW)			
	8 wk–6 mo	7–23 mo	2–10 y	10–18 y ^a
Bexsero ^b	Not indicated	Not indicated	Not indicated	Administer 2-dose series, 1 mo apart
Trumenbra ^b	Not indicated	Not indicated	Not indicated	Administer 3-dose series at 0, 1–2, and 6 mo apart

^aIf the patient has received one meningococcal vaccination (typically if >11 years), complete a 2-dose series if at least 8 weeks have passed after the first immunization. If patient has already received 2 doses, no further immunizations are necessary.

^bBexsero and Trumenbra are meningococcal serogroup B vaccines.

TABLE 237.4 Recommendations for Quadrivalent Meningococcal Immunization in Asplenic Children

Meningococcal MCV4	AGE AT ASPLENIA (ADMINISTER ONE VACCINE PRODUCT BELOW)			
	8 wk to 6 mo	7–23 mo	2–10 y	10–18 y ^a
Menveo ^b	Administer at 2, 4, 6, and 12 months of age	Administer 2-dose series 12 wk apart; give 2nd dose after 1 y of age	Administer 2-dose series ≥8 wk apart	Administer 2-dose series ≥8 wk apart
Menactra ^b	Not indicated	Not indicated	Administer 2-dose series ≥8 weeks apart	Administer 2-dose series ≥8 wk apart

^aIf the patient has received one meningococcal vaccination (typically if >11 years), complete a 2-dose series if at least 8 weeks have passed after the first immunization. If patient has already received 2 doses, no further immunizations are necessary.

^bMenveo and Menactra are quadrivalent (MCV4) meningococcal vaccines (A,C,Y,W-135 serogroups). Avoid use of Menactra in children <2 years because of interference with serologic response to pneumococcal conjugate vaccine; do not use Menactra within 4 weeks of pneumococcal conjugate vaccination.

Notes: (1) If the first meningococcal conjugate quadrivalent vaccine is administered at ≥7 years, a booster dose should be given every 5 years after completing the primary series (listed in Table 237.4). (2) If the first meningococcal quadrivalent vaccine is administered at ≤7 years, the first booster should be given 3 years after completing the primary series (listed in Table 237.4), and then every 5 years thereafter. (3) If a child began a series of Menveo or Menactra, then it is preferred that the series be completed with the same vaccine, but either may be substituted if needed. (4) The meningococcal quadrivalent (MCV4) and serogroup B vaccines may be administered together, but should be given in different locations (e.g., opposite arms).

antimicrobial prophylaxis should be considered for all children with asplenia younger than 5 years and for those at least 1 year after splenectomy.⁹ Penicillin is the agent of choice. Penicillin V given twice daily (125 mg twice daily for children younger than 3 years; 250 mg twice daily for children older than 5 years) significantly decreases the frequency of invasive pneumococcal infection. Erythromycin and TMP-SMX are alternative options in patients with documented hypersensitivity to penicillin. The duration of prophylactic coverage remains controversial; current practice is to provide penicillin prophylaxis indefinitely in immunocompromised patients, whereas the duration for other children is empirical.^{9,141} Children with sickle cell disease may have prophylaxis safely discontinued after 5 years of age.

Hemoglobinopathies

Functional asplenia is the primary reason for susceptibility to pneumococcal infection in children with sickle cell anemia. Serum immunoglobulins are normal or increased in these children; however, they have a dysfunctional alternative complement pathway and decreased opsonic activity (which is mediated by both the alternative and the classic complement components) against *S. pneumoniae*. Leukocyte function also is defective in patients with sickle cell anemia; intracellular production of hydrogen peroxide, respiratory stimulation, and hexose monophosphate shunt activity are inadequate during phagocytosis. In contrast, leukocytes from splenectomized patients without sickle cell anemia exhibit normal phagocytic function accompanied by adequate metabolic stimulation. Immunologic dysfunction occurs less rapidly and less commonly in children with hemoglobin C sickle cell anemia and hemoglobin C β-thalassemia.^{94,159}

Patients with sickle cell disease are at risk for development of overwhelming infection (septicemia and meningitis) by encapsulated bacteria, including *S. pneumoniae*, *H. influenzae* type b, and, rarely, *N. meningitidis*. *S. pneumoniae* is the most important and frequent cause of septicemia and meningitis in these patients.¹⁵⁹ The risk is particularly high in children younger than 3 years.⁶⁵ A trend toward increased frequency of invasive disease in the first 2 to 5 years after splenectomy also has been noted. Unlike very young children, school-aged children appear to be less vulnerable to pneumococcal invasive infection, even though they remain functionally asplenic.^{66,159,164}

The efficacy of penicillin prophylaxis in preventing pneumococcal infection in infants and young children with sickle cell disease has been well documented in several reports.^{9,57,65,66,123,164} A Cochrane review of prophylactic penicillin use in children with sickle cell anemia demonstrated a 63% reduction in pneumococcal infection, although the risk for infection was low overall, particularly after the age of 5 years.⁷⁷ Adverse effects were rare and minor.

The recommended dose of penicillin V is 125 mg twice daily in children younger than 3 years and 250 mg twice daily in children 3 years or older. Some physicians recommend use of amoxicillin (20 mg/kg per day) or TMP-SMX (4 mg TMP plus 20 mg SMX per kilogram daily) in children younger than 5 years to include coverage against *Haemophilus* organisms, which are less likely to be a concern in children who are immunized adequately. A systematic review assessing medication adherence in children with sickle cell anemia found increased adherence to prophylactic antimicrobials prescribed via the intramuscular compared with the oral route (90% vs. 44%). Overwhelming sepsis, infections overall, and emergency department visits were associated with antimicrobial nonadherence.¹⁵⁶

Because overwhelming infection can occur in infants as young as 3 months, detection of sickle cell anemia should be accomplished in the neonatal period. Infants in whom sickle cell anemia is diagnosed should start a prophylactic antibiotic regimen no later than 3 to 4 months of age.⁶⁶ The optimal duration of prophylaxis is not defined clearly, and the age at which prophylactic penicillin can be discontinued safely is determined arbitrarily.⁹ A concern is that penicillin prophylaxis may decrease the development of natural immunity against pneumococcal infection in children receiving prophylaxis, thereby rendering them more susceptible to development of infection after prophylaxis is discontinued.³³ Another concern is the accelerated development of penicillin-resistant strains of *S. pneumoniae*.^{58,159} A multicenter study by the Prophylactic Penicillin Study II group suggests that in children with sickle cell anemia who have not had a previous severe pneumococcal infection or surgical splenectomy and are receiving comprehensive care, prophylaxis may be stopped safely at 5 years of age.⁵⁸ Continuous prophylaxis has limitations, and serious overwhelming infection can occur while patients are receiving prophylaxis. Patients or parents (or both) should be aware that any febrile illness is potentially serious, and immediate medical attention should be sought.^{43,123}

Cerebrospinal Fluid Leakage

The value of antibiotic prophylaxis in patients with cerebrospinal fluid leakage has not been proved.^{63,108} In the absence of meningeal inflammation, many antibiotics do not penetrate the blood-brain barrier and do not attain adequate levels in cerebrospinal fluid. Antibiotic prophylaxis often fails and frequently alters the normal flora of the respiratory tract, thereby resulting in colonization with resistant bacteria. Prophylaxis may be considered for a short duration while surgical repair is being planned.¹⁰⁸

SURGICAL PROPHYLAXIS

The goal of prophylactic administration of antibiotics before or during surgery is to reduce or eliminate postoperative morbidity, shorten hospitalization, and reduce the overall costs attributable to infection. Wounds can be classified as clean, clean-contaminated, contaminated, and dirty. Table 237.5 provides the conditions for these wound categories. Dirty wounds are those with purulence, abscess, or preoperative perforation of the gastrointestinal, oropharyngeal, biliary, or tracheobronchial tracts or penetrating trauma with environmental flora. The appropriate doses for children (by weight) are provided in Table 237.6.³

An effective prophylactic regimen should be directed against the most likely infecting organisms but need not eradicate every potential pathogen. Therefore, for most procedures, the first-generation cephalosporin cefazolin, which is active against many streptococci and staphylococci, remains effective. When operations involve the bowel with exposure to aerobic and anaerobic bowl flora, then several agents, including second-generation cephalosporins (cefoxitin, cefotetan) or ampicillin/sulbactam, may suffice alone, or combinations such as cefazolin with metronidazole may be substituted; vancomycin can be used for prophylaxis when frequent infections with MSRA are prominent, but it may not be more effective than cefazolin, and persistent use may lead to the emergence of vancomycin-resistant organisms. It is common practice to give antibiotics at the time of anesthesia induction, which should result in adequate tissue and serum levels at the time of incision and intraoperative tissue manipulation. For most procedures lasting less than 4 hours, a single dose is recommended. Published studies often use one or two additional doses after the completion of surgery, but most experts do not believe that these are necessary, and no data support the use of antibiotics beyond 48 hours.

General Surgical Procedures

Skin incision, organ manipulation, and surgical trauma increase the likelihood for development of local infection. Surgical procedures traditionally are classified as clean, clean-contaminated, and contaminated (see Table 237.5). A fourth category of dirty wounds includes those known to be contaminated, when before surgery the skin or visceral

space was compromised, introducing normal bowel or skin flora, or by contamination with a large number of environmental bacteria. Prophylactic antibiotics are effective in reducing postoperative infections after contaminated and clean-contaminated surgical procedures, whereas their efficacy is more controversial for clean surgical procedures. Clean surgical procedures generally carry a risk for development of postoperative wound infection that is less than 5% and, in many hospitals, less than 1%.

The critical period for development of infection is short, and optimal prophylaxis should be restricted to the perioperative period. Antibiotic prophylaxis of less than 24 hours' duration is effective both clinically and experimentally. Administration of antibiotics should be started at the time of induction of anesthesia or immediately before the surgical incision is made and discontinued within 24 hours. A 5-year retrospective review of nearly 250,000 pediatric surgical procedures demonstrated that only 82% of children in whom prophylaxis was warranted received prophylaxis and 40% of patients received prophylaxis when none was indicated. Risk of *Clostridium difficile* was fourfold higher in those children receiving antimicrobial prophylaxis.¹³⁰

Addressing all situations of surgical prophylaxis is beyond the scope of this chapter, and the reader is referred to several publications and reviews on the subject.^{49,76,84,86,125,151,154} Nationwide standards and goals for surgical prophylaxis have been established.²⁹ The consensus of these statements is that effective surgical prophylaxis must include the first dose of antimicrobial agents within 60 minutes before the surgical procedure and that dosing should be discontinued within 24 hours after the end of surgery. These documents and others provide the routine basis and evidence base for all current guidelines on surgical prophylaxis, including the recommended regimens and dosing for cardiothoracic, vascular, and abdominal or colonic surgery, as well as hip or knee arthroplasty, vaginal or abdominal hysterectomy, and neurosurgical procedures.¹⁵

Neurosurgical Procedures

The use of prophylactic antibiotics for clean neurosurgical procedures remains controversial.^{64,70,108,127} However, because of the perceived benefits of prophylactic antibiotics in uncontrolled trials involving a large number of patients, of whom adults were the majority, and in view of the scarcity of definitive studies, current recommendations support the use of a short-course prophylactic regimen.^{34,54,68,126,161} Prophylaxis for clean neurosurgical procedures is particularly valuable for high-risk groups (e.g., patients undergoing operative procedures in excess of 4 hours, operations in which craniotomies are performed, or patients with major underlying disease).^{35,50,136}

Placement of cerebrospinal fluid shunts is one of the most common neurosurgical procedures in pediatric patients. An estimated 10,000 new shunt insertions and 6000 revisions are performed annually in the United States. The frequency of shunt infection varies from 1.5% to 39% (average, 10–15%).^{91,131} The major route of infection is colonization of the device or the operative wounds during placement.⁶⁸ Retrograde spread from the distal end of the catheter or hematogenous seeding accounts for some instances of infection.

Most infections are noted within 15 days to 2 months of shunt placement.^{95,131} Commensal skin flora are the predominant pathogens. Coagulase-negative staphylococci are the most common pathogens and account for approximately 70% of shunt infections. *S. aureus* is less common. Gram-negative bacilli are the least common and often are the result of retrograde infection from the peritoneum.^{91,131}

The role of prophylactic antibiotics for placement of cerebrospinal fluid shunts has been controversial.⁶⁹ A meta-analysis of 1359 patients in 12 randomized, controlled trials indicated that short-term perioperative antimicrobial prophylaxis at the time of placement of a cerebrospinal fluid shunt significantly decreases the risk for subsequent development of device-related infection.⁹⁵ Various antimicrobial regimens, including antistaphylococcal penicillins, cephalosporins, TMP-SMX, vancomycin, gentamicin, and combinations, were used in these trials. The choice of an appropriate prophylactic regimen in a particular setting should be based on the local epidemiology of suspected pathogens, local patterns of antimicrobial susceptibility, cost, and expected toxicity. The duration of perioperative prophylaxis should not exceed 48 hours.^{88,95} A longer

TABLE 237.5 Surgical Procedures and Probable Pathogens	
Surgical Category	Most Likely Pathogens
Clean	
Neurosurgical	CNS, <i>Staphylococcus aureus</i>
Cardiovascular	CNS, <i>S. aureus</i>
Orthopedic	CNS, <i>S. aureus</i>
Clean-Contaminated	
Burn	Group A streptococci, <i>S. aureus</i> , GNB
Gastrointestinal	GNB, anaerobes, enterococci
Urogenital	GNB, enterococci
Respiratory	α-Hemolytic streptococci, anaerobes
Contaminated	
Ruptured viscera	GNB, anaerobes, enterococci
Traumatic wounds	<i>S. aureus</i> , group A streptococci, clostridia

CNS, Coagulase-negative staphylococci; GNB, gram-negative bacilli.

TABLE 237.6 Preoperative Antimicrobial Prophylaxis

Type of Surgery	Antimicrobial Agents	Dose	Type of Surgery	Antimicrobial Agents	Dose
Neonatal (≤ 72 h old)	Ampicillin Gentamicin	50 mg/kg 2.5 mg/kg	Genitourinary	Ampicillin <i>plus</i> Gentamicin <i>or</i> Cefazolin	50 mg/kg 2 mg/kg 30 mg/kg
Cardiac	Cefazolin Vancomycin ^a	30 mg/kg 15 mg/kg	Head and neck ^b	Clindamycin <i>with or without</i> Gentamicin <i>or</i> Cefazolin <i>plus</i> Metronidazole	10 mg/kg 2.5 mg/kg 30 mg/kg 15 mg/kg
Gastrointestinal			Neurosurgery	Cefazolin <i>or</i> Vancomycin ^a	30 mg/kg 15 mg/kg
Gastric/esophageal	Cefazolin ^b	30 mg/kg	Ophthalmic	Gentamicin, ciprofloxacin, Ofloxacin, moxifloxacin, Tobramycin <i>or</i> Neomycin-gramicidin- polymyxin B <i>or</i> Cefazolin	Multiple drops topically 2–4 hours prior to surgery Multiple drops topically 2–24 h before surgery 100 mg subconjunctivally
Biliary	Cefazolin	30 mg/kg	Orthopedic ^f	Cefazolin <i>or</i> Vancomycin ^a	30 mg/kg 15 mg/kg
Colorectal/appendix ^c	Cefoxitin <i>or</i> Metronidazole <i>plus</i> Gentamicin <i>or</i> Cefazolin <i>plus</i> Metronidazole <i>or</i> Clindamycin <i>plus</i> Gentamicin <i>or</i> Ciprofloxacin Cefoxitin <i>with or without</i> Gentamicin <i>or</i> Gentamicin <i>plus</i> Metronidazole <i>plus</i> Ampicillin <i>or</i> Meropenem	40 mg/kg 15 mg/kg 2.5 mg/kg 30 mg/kg 15 mg/kg 10 mg/kg 2.5 mg/kg 2.5 mg/kg 10 mg/kg 50 mg/kg 20 mg/kg	Thoracic	Cefazolin <i>or</i> Vancomycin ^a	30 mg/kg 15 mg/kg
Ruptured viscus ^d					

^aIf MRSA is a consideration.

^bFor certain high-risk conditions (e.g., decreased gastric acidity, poor intestinal motility, esophageal obstruction).

^cUncomplicated/no perforation.

^dTreatment required as well; may use the same agents.

^eIncision through oral or pharyngeal mucosa.

^fInternal fixation of fractures, spinal procedures with and without instrumentation, implantation of prosthetic materials.

Note: Selection of appropriate antimicrobial agents for surgical prophylaxis must take into account patient-specific and institutional-specific resistance patterns as well as the likelihood of colonization with specific organisms.

Modified from Antimicrobial prophylaxis. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:959–974.

duration of prophylaxis increases cost and the risk for development of adverse reactions and promotes alteration of the normal flora and the emergence of resistant bacteria.

Cardiovascular Surgery

Infectious complications of cardiovascular surgery can be very serious and life-threatening, and antimicrobial prophylaxis is used commonly in most medical centers.^{87,92} Most available data are based on reports from adult patients,^{42,71} with little specific information available on prophylactic antibiotic use in pediatric patients. The goal of prophylactic therapy is prevention of wound infection, mediastinitis, and endocarditis. A survey of 43 North American academic centers with pediatric cardiovascular surgery programs indicated that all centers use prophylactic antibiotics for all operative procedures.⁹⁷ Monotherapy prophylaxis was used by 91% of respondents and consisted almost exclusively of a first- or second-generation cephalosporin. In 95% of centers, prophylaxis was started just before surgery or intraoperatively. Prophylaxis was continued for 48 hours or less in most (68%) instances. Prophylactic antibiotics often were continued while thoracostomy tubes, mediastinal tubes, or transthoracic vascular catheters were in place but usually not for

endotracheal tubes, arterial or percutaneous central venous catheters, or temporary pacing wires. A prospective analysis using historical controls of 283 neonates undergoing cardiac surgery (mean age, <2 weeks) demonstrated no increased risk for surgical site infections when perioperative antimicrobial prophylaxis was limited to 48 hours in infants with a closed sternum¹¹¹.

Table 237.6 provides the current antibiotics and dosages recommended for surgical prophylaxis by type of surgery. It is recommended that a single dose be used for prophylaxis and that it be given 1 to 2 hours before surgery to ensure that adequate levels are present in tissue at the time of the initiation of the procedure. For those agents that require longer administration times such as vancomycin, administration of the dose should be at least 2 hours before the procedure. Recommendations are generally for only a single dose, but adequate levels should be maintained throughout the procedure; therefore repeated doses during a long procedure should be given if the procedure extends beyond 2 times the half-life of a drug, such as cefazolin, which would require repeating the dose in 3 to 4 hours. Duration of the antimicrobial agents is never to extend more than 24 hours after the initiation of the procedure.

Outpatient Intravenous Antimicrobial Therapy for Serious Infections

Alice L. Pong • John S. Bradley

Outpatient parenteral antimicrobial therapy (OPAT) is the means by which children can receive the benefits of parenteral (intravenous or intramuscular) therapy in an outpatient setting, usually the home, avoiding hospitalization with the associated exposure to nosocomial pathogens, inpatient costs, and psychological stress for child and family. The widespread acceptance of OPAT by physicians, families, and insurers

has led to a tremendous increase in the outpatient treatment of serious infectious diseases.* Madigan and colleagues reported 2.5% of hospital discharges in a 17-month period involved OPAT.³⁹ However, this increased prevalence of OPAT has not necessarily been associated with increased

*References 5, 19, 20, 24, 27, 30, 38, 41, 43, 44, 48, 49, 51, 52, 55, 59.

support for formal OPAT programs. Surveys among adult and pediatric infectious disease providers report significant inconsistency in the level of resources, oversight, and expectations associated with OPAT at different institutions.^{4,42} The standard of care provided to children through OPAT should equal or surpass that provided to hospitalized children. National guidelines for OPAT in adults and children have been published by the Infectious Diseases Society of America and define both benefits and risks.⁶⁰ This chapter explains the basic concepts behind OPAT for children in order to achieve the same outcomes of parenteral therapy provided in an inpatient setting. It should be considered unethical to limit resources and place the child at increased risk for complications of the infection or therapy, particularly in an effort to save money by insurers or institutions. The OPAT team, which includes the physician, OPAT coordinator, nurse, pharmacist, parent or caregiver, and third-party payer, needs to work closely to ensure a successful outcome for the child.

EVALUATING A CHILD AND PARENTS FOR OUTPATIENT PARENTERAL ANTIMICROBIAL THERAPY

Broad criteria are used to determine the medical feasibility of using OPAT (Box 238.1). The most important aspect in the assessment of a newborn, infant, or child for OPAT is a determination that ongoing parenteral therapy is required to treat the infection appropriately and continuous skilled nursing observation and care are not required for management. Development of complications of the infection in the child should be considered highly unlikely by the time OPAT is undertaken; unskilled clinical observations by the parents or caregivers should be considered adequate for care. Additional significant risk should not be placed on the child's recovery by enrollment in an OPAT program. Whenever possible, oral antibiotic therapy should be used instead of parenteral therapy. Kovacich and colleagues³⁵ reported that 32% of pediatric patients with complications related to a peripherally inserted central catheter (PICC) treated with OPAT, on review, could have had intravenous antibiotics discontinued before discharge from the hospital. Options for oral therapy include agents such as the fluoroquinolones ciprofloxacin and levofloxacin, and an oxazolidinone, linezolid, that have excellent absorption and tissue exposure characteristics but may have some potential toxicities that may not be present with older generic parenteral antibiotics. The use of oral fluoroquinolones over parenteral therapy if no other class of oral agent is available is supported by the American Academy of Pediatrics Committee on Infectious Diseases. Pediatric safety data exist for both levofloxacin⁹ and moxifloxacin.¹¹

BOX 238.1 Medical and Social Criteria for Outpatient Parenteral Antimicrobial Therapy (OPAT)

Medical Criteria for OPAT

- Medical diagnosis of infection with a suspected or documented pathogen
- Clinical response to antiinfective therapy (if therapy is started in the hospital)
- No assessed need for urgent medical, surgical, or laboratory interventions to achieve a clinical response to antiinfective therapy
- No significant risk for complications of the infection
- No requirement for continuous skilled nursing care

Social Criteria for OPAT

- Parents interested and motivated
- Parents capable of assessing the child for complications of infection and therapy
- 24-hour telephone access to the OPAT team
- Transportation for timely return to the clinic or hospital, if needed
- Home environment acceptable and resources available
- Parents documented to be capable of administering parenteral antiinfective agents, if required, before OPAT begins

A child usually is prescribed an OPAT regimen from either a hospital setting after inpatient intravenous therapy or an outpatient setting such as a clinic or emergency department. For a child being discharged from the hospital, an unequivocal response to parenteral antiinfective therapy should be demonstrated. Most often, appropriate cultures will have directed the use of antiinfective therapy active against the isolated pathogens. For children with no positive cultures, the signs and symptoms of the infection should be resolving with empirical therapy, as demonstrated by decreasing fever, improving function, and improvement in inflammatory markers. The child's infection should be judged by the clinician to be unlikely to progress or to result in complications. No further surgical or medical interventions should be anticipated during the remainder of the parenteral antimicrobial therapy course.

The child's clinical course during receipt of OPAT needs to be monitored to be certain that the anticipated response continues to occur. An outpatient visit usually is scheduled for a few days after discharge.

Before a child is enrolled in OPAT, an assessment of the parents or caregivers also is required (see Box 238.1). Because the parents are responsible for the nursing care of their child in the home, they must be willing and capable participants. Although most parents are very interested and highly motivated to return home with their child, not all are willing to perform or are capable of performing the required nursing functions. Work and school schedules may conflict with timely administration of antibiotics. Most parents are capable of providing limited medical assessment of their children, but, unfortunately, some are not. In addition, the home environment should have the resources required for the proposed medical care. For example, intravenous therapy administered to a child through a tunneled, central catheter requires specified conditions for antiinfective drug infusions and dressing changes, including the availability of a clean room with running water, and a refrigerator if storage of antimicrobials and diluents is necessary. Less stringent criteria clearly would apply for a child visiting the outpatient clinic daily to receive intramuscular antibiotic injections. Communication between the parents and medical personnel is essential. For parents or caregivers, telephone access to nurses and clinicians is critical. In addition, the parents should be able to bring their child back to the hospital or clinic for reevaluation if complications arise either from the infection or from therapy. Hence, access to adequate transportation within a medically appropriate time frame is required. Families with no available transportation, families who live in rural areas located several hours' travel from a medical facility, and OPAT during the winter season in which weather conditions may severely limit travel all should be considered before OPAT is started. In addition to observing their child and communicating information to medical providers, many parents may be asked to infuse antiinfective agents intravenously into their children. Doing so requires an additional level of skill in the parent or caregiver and assessment of parental competence for this function by the OPAT nursing and medical personnel.

OUTPATIENT PARENTERAL ANTIMICROBIAL THERAPY PROGRAM

The roles of physicians, OPAT coordinators, nurses, pharmacists, and parents or patients have been defined previously (Table 238.1).⁶⁰ When the clinician considers that the child's condition is sufficiently stable to pursue intravenous outpatient therapy from a hospital ward, a clinic, or an emergency department setting, the coordinator of the outpatient treatment program is notified. In facilities where there is no formal OPAT program, different aspects of this role may be filled by multiple people, including a hospital case manager, homecare coordinator, and/or clinic nurse. This person is capable of assessing the feasibility of implementing OPAT for that particular child and family and assessing reimbursement by third-party payers and obtaining authorizations, if needed. Insurance companies may require a much greater financial contribution by families for the cost of care after a child is discharged, in contrast to their obligation for ongoing inpatient hospital charges. The OPAT coordinator interviews parents and medical staff to determine the parents' willingness and their abilities to administer medications and to assess the home environment. After the clinician prescribes the

antiinfective agents, required nursing visits, ongoing laboratory and imaging tests, and follow-up clinic visits, the OPAT coordinator puts together the resources required for successful therapy. With knowledge of the parents' abilities and resources, the medication and equipment requirements, and the home nursing visits required, the coordinator makes the final determination about the feasibility of the program. An example of an OPAT physician's order form that includes catheter management and medication orders, laboratory and imaging test orders, and clinic visits is shown in [Fig. 238.1](#). These orders usually are included in hospital discharge orders and are often incorporated into the electronic medical record. The coordinator of the OPAT program, whether it is clinic or hospital based, should ensure that open lines of communication exist among the clinician, the home visiting nurse, the pharmacist, and the parents. All members of the OPAT team should be aware of their responsibilities. A defined, written plan for medical and nursing care should be established, a physician should be identified who is responsible for managing the infection and any potential complications related to OPAT. It is critical that both parents and members of the OPAT team have access to this physician or the physician's designee for questions about the infection and therapy, and that this physician is clearly identified (and is aware of the responsibility) before discharge, to allow questions to be answered and decisions to be made on the need for urgent evaluation at a medical institution (clinic or emergency department). In many centers, the physician discharging the patient from the hospital may not be the physician responsible for outpatient management. Communication between providers is critical. Although infectious disease consultation is reported to improve appropriate selection of antimicrobial agents,¹ most institutions do not require infectious disease consultation for OPAT to be prescribed. The physician assuming care of the patient should understand any potential complications of OPAT that might arise.

OPAT may be provided by periodic visits to the clinic, emergency department, or day infusion center²⁴ or be provided in the home by visiting nurses and parents. For children receiving therapy at home, the frequency of the required home pediatric nursing visits needs to be individualized for each child and depends on many factors—the clinical course while the child is receiving therapy, the seriousness of the infection, the ability of the parents to effectively examine the child, and the risk for development of complications that can be related to either the

infection or therapy. For most children, home nursing visits are performed weekly and are accompanied by catheter dressing changes. For some patients, more frequent visits may be required, especially at the beginning of OPAT. After treatment at home has been delivered as anticipated and recovery from infection is proceeding as expected, visits may be decreased to once each week, particularly if the parents have demonstrated competency in providing nursing care, including managing an intravenous catheter, changing wound dressings, and providing clinical assessment. The home visiting nurse also may have the opportunity to establish ongoing assessment of the parents' ability to administer antiinfective agents in the home.

Physical assessment of neonates receiving OPAT may be particularly difficult for parents, and daily visits throughout the entire course of therapy by skilled pediatric home visiting nurses may be required. Daily visits also are important for children with less stable infections, such as central nervous system infections, because subtleties in the neurologic examination findings may not be appreciated by parents or caregivers and may provide clues to impending problems. Nursing aspects of pediatric OPAT have been outlined by successful programs.^{30,38,56}

Pediatric competency in nursing is not standardized. Each state government in the United States licenses nurses on the basis of criteria specific for that state. However, just as for inpatient pediatric care, pediatric experience is an important qualification for the home visiting nurse caring for children. Unfortunately, home nursing agencies providing care to children are not required to have expertise in pediatric nursing. Therefore considerable discrepancy exists in pediatric competency among nursing agencies. Given the importance of pediatric expertise in evaluation and management of infected children in the home, the home nursing agency contracted to provide care is expected to have personnel with training and experience equivalent to that of nurses providing care in a pediatric inpatient setting. The home nursing agency should be able to document proficiency in delivering care to newborns, infants, and children to the clinician and the OPAT coordinator.

In many states, only licensed nurses (registered nurses and licensed vocational nurses) may infuse antiinfective agents. However, most states have no rules prohibiting parents from administering drugs. Accordingly, parents may be expected to infuse medications to their children if licensed nurses are not deemed by the home care agency and the physician to be necessary to provide this function. The physician should be aware

FIG. 238.1 An example of a physician's order sheet for outpatient intravenous antimicrobial therapy (OPAT) for serious infections at Rady Children's Hospital San Diego, California.

of the qualifications of the personnel responsible for the intravenous infusion of antiinfective agents.

The home visiting nurse should communicate with the physician about the medical status (e.g., the medical stability) of the child and plans for follow-up, before OPAT is started. Analogous to inpatient care, the nurses and physicians are expected to be on-call 24 hours each day.

Similarly, the pharmacist providing antiinfective therapy for OPAT should be familiar with the dosages and side effects of therapy provided to all pediatric age groups, from newborns to adolescents. Dosing errors in infants and children are not uncommon occurrences in health care facilities, given the broad range of doses administered.³³

The parents should have written instructions for the tasks they are required to perform in the home, including information on sterile technique, administration of antimicrobials through sterile tubing and valves, flushing of catheters, and dressing changes. Their proficiency in management of the catheter and infusion of antiinfective agents should be demonstrated before the child is discharged from the hospital, emergency department, or clinic because some parents or caregivers may not be capable of performing these tasks adequately. Telephone numbers should be provided for the 24-hour on-call nursing and physician personnel. A list of complications of the medications and information on how the parent should perform a clinical assessment of the child's infection should be provided, along with a set of parameters requiring immediate notification of medical personnel. Plans for disposal of needles, dressings, and other medical waste also should be made before the child is sent home.

Visits to clinicians (i.e., primary care providers, surgeons, subspecialists) are scheduled as necessary according to the clinical status of the child and the degree of expertise required by the examiner. If the child is stable in an outpatient setting, the treating physician should determine the frequency of routine follow-up clinic visits unless the home visiting nurse or parent observes problems requiring more immediate attention. For any high-risk, relatively unstable child, daily physician visits may be important, particularly if skilled pediatric home nursing is not available; however, if daily physician visits become necessary, the value of OPAT versus inpatient hospitalization should be reassessed.

Although abuse of intravenous access seldom occurs, for an adolescent who may have a history of alcohol or drug dependence, the clinician should be particularly cautious in approving OPAT. For younger children with indwelling catheters, Münchausen syndrome by proxy may be a concern for infants and children who do not recover clinically as anticipated or have repeated unanticipated complications.

INFECTIONS SUITABLE FOR OUTPATIENT PARENTERAL ANTIMICROBIAL THERAPY

Virtually any infection can be treated by OPAT at some point in the course of therapy by following the criteria listed in [Box 238.1](#). For each child, a thorough assessment of the risks for development of complications of the infection must be made before outpatient therapy is considered. A partial list of infections treated with OPAT is given in [Table 238.2](#); most of the studies are not prospective, randomized investigations comparing children receiving therapy in the hospital with those receiving therapy outside the hospital. Studies show the most common infections in pediatrics treated with OPAT are bone and joint, bloodstream, pulmonary, and gastrointestinal infections.^{1,23,39} Other infections that have been treated with OPAT at some point include endocarditis; central nervous system infections, including meningitis, epidural abscess, subdural empyema, and brain abscess; urinary tract infections; upper respiratory tract infections, including severe acute otitis media, chronic suppurative otitis, and mastoiditis; fever with or without neutropenia in low-risk immunocompromised children; neonatal bacterial sepsis; and postoperative wound infections.

DELIVERY OF ANTIMICROBIAL THERAPY

Selection of an Antimicrobial Agent

Selection of antimicrobial therapy for OPAT is similar to selection of therapy for any child in that the primary goal is to achieve clinical and

microbiologic cure with the most efficacious, least toxic, and most cost-effective agents. Selection of an agent that is more convenient to administer but that may not be as effective is not appropriate. However, of the agents that demonstrate equivalent activity against the child's pathogen, the preferred agent is the one that is given least frequently, is nontoxic, and requires the least frequent monitoring for adverse events. Preferred agents for the most common community-acquired pathogens are given in [Table 238.3](#). Almost any pathogen, community acquired or nosocomial, bacterial, fungal, or viral, can be treated in the home if the medical and social criteria for OPAT can be met.

In general, β -lactam agents (i.e., penicillins, cephalosporins, and carbapenems) require less frequent monitoring than do aminoglycosides (i.e., gentamicin, tobramycin, and amikacin), glycopeptides (i.e., vancomycin, dalbavancin, oritavancin or telavancin), or oxazolidinones (e.g., linezolid or tedizolid). Agents that can be given intravenously during the course of a short period (5–15 minutes), such as β -lactam agents, are preferred to those that require up to an hour with each infusion (e.g., aminoglycosides and glycopeptides). Agents that can be given intramuscularly if intravenous access is temporarily lost are preferred to those that may be given only intravenously. Not only are these parameters designed to provide the optimal clinical outcome with minimal toxicity, they also are designed to facilitate therapy in the home. Dosing more frequently than every 8 hours poses a formidable challenge to many families, particularly those without extensive family support. Administration of two or three antibiotics that each require dosing three or four times each day is virtually impossible for most families to accomplish. These parameters are designed to maximize the potential for parents to be able to provide care at home with minimal risk. Although more frequent nursing visits may provide relief to parents, this is not always economically or logistically feasible. The charge for multiple nursing visits each day approaches the cost of a day in the hospital for a stable child, and most agencies do not have sufficient staff to provide more than one visit each week to a family.

Depending on the agent used, monitoring for antimicrobial toxicity in the outpatient setting should occur with the same frequency as that in the inpatient setting. Monitoring of renal function and serum antibiotic

TABLE 238.3 Selection of Antimicrobial Agents for Common Pathogens in Community-Acquired Infections

Pathogen	Antimicrobial Agent	Dosing Frequency (h)	Toxicity
Gram-Positive Bacteria			
<i>Streptococcus pneumoniae</i>	Penicillin G ^a	6	
	Ampicillin ^a	6–8	
	Cefuroxime ^a	8	
	Cefotaxime ^a	6–8

	Imipenem-cilastatin	6–8	Central nervous system irritability in children with underlying central nervous system inflammation
	Piperacillin-tazobactam ^a plus an aminoglycoside ^c	Piperacillin-tazobactam: 6 Aminoglycoside: see above	Renal toxicity, ototoxicity (aminoglycoside)
<i>Neisseria meningitidis</i>	Ciprofloxacin ^d	8–12	Possible arthropathy
	Ceftriaxone ^b	24	
	Penicillin G	6	
Fungal Pathogens			
<i>Candida</i>	Fluconazole IV ^b	24	
	Amphotericin B (lipid preparations are better tolerated)	24, or every other day; may return to infusion center for each injection to manage side effects	Fever, chills, anemia, hypokalemia, decreased glomerular function
	Caspofungin or micafungin	24	
Viral Pathogens			
Herpes simplex virus	Acyclovir	8	Neutropenia, renal toxicity
Cytomegalovirus	Ganciclovir	12–24	Neutropenia

^aIf organisms are documented to be susceptible.^bPreferred agents based on dosing frequency and side effects.^cRequires monitoring of renal function and serum concentrations.^dNot indicated for therapy unless no other therapy options exist.

concentrations is important for children being treated with aminoglycosides or vancomycin. For children receiving long-term β -lactam therapy, periodic monitoring of the peripheral white blood cell count and renal and hepatic function every 2 to 4 weeks may detect the uncommon but well-described antibiotic-mediated toxicities of this class of antibiotics before any clinical manifestations occur.

Delivery of Antimicrobial Agents

OPAT can be delivered by intramuscular or intravenous injection. In general, the need for more than two or three injections per day necessitates intravenous therapy. However, once-daily intramuscular therapy lasting 1 week or longer has not been associated with short-term complications in anecdotal reports.^{7,8} Short polyethylene catheters normally used for inpatient intravenous therapy may be used for short-term therapy lasting less than 5 to 7 days.²⁴ On occasion, intravenous access will be lost, and the child will need to be reevaluated for ongoing parenteral therapy; if clinical improvement exceeds expectations, an early switch to oral convalescent therapy may be possible. If not, intravenous access may need to be reestablished. It may be performed in the home but more often will require the child and parent to return to the clinic or hospital. An intramuscular injection or injections may be given temporarily in the home, clinic, or emergency department until the intravenous catheter can be replaced.

For therapy lasting longer than 5 to 7 days, central catheters are preferred. PICC lines are widely available, practical, and cost-effective and have become the intravenous access of choice for extended therapy.^{28,41,59,61} These catheters may be inserted through many different peripheral sites (usually the antecubital vein) by physicians or nurses with training in the placement of central catheters. Sedation usually is required for younger infants and children. Alternatively, more traditional subcutaneously tunneled central catheters with one or more ports (e.g., Hickman or Groshong) may be placed by a surgeon in the operating room with the child under general anesthesia. These tunneled catheters, which also may be used for blood sampling, are preferred for children requiring parenteral nutrition or other parenteral medications in addition to antimicrobials. Each type of central catheter requires sterile techniques for accessing the catheter and close monitoring of the catheter exit site during administration of therapy. The home visiting nurse agency should have written protocols for the care and use of central catheters that are consistent with standards set by The Joint Commission, which provides a program for Home Care Accreditation.⁵⁸ Complications associated with PICC lines include infection, occlusion, dislodgement, breakage, phlebitis, infiltration, leakage, and thrombosis.³⁵ Risk factors for complications include younger age, noncentral PICC tip location, discharge to a long-term care facility, and public insurance.³⁵

Antimicrobial agents may be infused directly into the catheter by the caregiver by way of an antibiotic-containing syringe simply attached to the catheter hub ("IV push"), followed by flushing of the catheter with saline or a heparin-containing solution. This method is often used for β -lactam agents. Alternatively, particularly for agents that cannot be infused quickly, an intravenous drip system must be used, or the agent must be infused by a pump. Pumps come in three basic designs: those with no electronic or moving parts; syringe pumps, in which the syringe containing the antimicrobial agent is placed in a motorized pump designed to administer the dose during the course of a certain period; and electronic programmable pumps, which may have a variety of pump mechanisms and are programmed to control infusions of one or more agents administered during the course of different periods.

The least expensive pumps are those with no moving parts. One type of pump requires injection of the antibiotic solution, under some pressure, into a thick elastomeric "balloon." The pressure used to inject the antibiotic into the balloon then pushes the antibiotic through an infusion rate-limiting valve into the intravenous line and subsequently into the child. Other types of pumps are designed to place the antibiotic solution into a bag that then is placed into a device in which spring-loaded plates press on the solution contained in the bag, again pushing the antibiotic into the child through an infusion rate-limiting valve. These pumps generally use disposable infusion containers and are adequate for treatment with a single antibiotic administered up to a few times each day.

New tools for OPAT are becoming available each year. Resource guides to the equipment used for OPAT are available.⁴⁷ Unfortunately, for children, most of the equipment and resources available are designed for adults.

OUTCOME ANALYSIS

The anticipated outcome in the treatment of an infection is clinical and microbiologic cure with no complications of therapy. OPAT program outcomes should be evaluated at regular intervals by the entire OPAT team to determine whether local criteria for the OPAT program have provided the same standard of care as that in the hospital and offer opportunities for improved quality of care. Although the psychosocial benefits of OPAT for children from a secure home environment were the original impetus for the establishment of pediatric programs, the economic benefits of outpatient therapy have been easier to document for both adults and children, although current published data in children are sparse.^{5,10,25,26,29,32,43,63,67,69} The cost of treatment is substantially less for outpatient therapy when neither hospital facilities nor 24-hour skilled nursing care is necessary. With shorter periods of hospitalization associated with OPAT, the risk for acquiring a nosocomial viral or bacterial infection should diminish and further decrease the overall cost of care.

However, complications may occur in children receiving OPAT, just as they occur in inpatients.^{16,23,24,31,37,50} The infection being treated may not be under control or may relapse while the child is being monitored by parents or home nursing personnel. Errors in antibiotic dosing and administration may occur,³³ particularly if parents are given the responsibility of preparing and administering antibiotics in the home. Complications of antimicrobial therapy, including adverse drug reactions, may increase when the number of antimicrobial agents and doses administered to a child increases. Gomez and colleagues²³ reported catheter complications in 29% and adverse drug reactions in 29% of children receiving OPAT. Madigan and Banerjee also reported 29% of pediatric OPAT patients with catheter or drug related complications.³⁹

In another pediatric study of children receiving long-term therapy for osteomyelitis, 51% of courses in 54 children were associated with adverse drug events.¹⁶ Catheter- and pump-related complications often arise during therapy, with 26% of 98 children in one study having catheter complications, most commonly occlusion or clotting and dislodgement, also related to longer duration of therapy.^{28,31,50} Parents may not be compliant with clinic visits and may not be in the home when the home nursing agency has scheduled a visit. Family members or neighbors other than those trained to care for the child may provide care without the knowledge of the home nursing agency or physician. The clinician may need to rehospitalize the child if doing so is required to complete parenteral therapy safely.

TJC publishes standards and reviews home care outcomes by evaluating specified parameters, including unscheduled inpatient admissions, early discontinuation of parenteral therapy, interruptions in parenteral therapy, catheter-related infections, and adverse drug reactions.⁵⁷

Until recently, data on outcomes from various home nursing agencies were not made available to contracting physicians, hospitals, or payers. Outcome data now are required to be collected by home health organizations, which eventually will help standardize the assessment of OPAT programs. The physician or OPAT coordinator should request outcomes data from any home nursing agency proposing to care for a child by OPAT.

SUMMARY

Successful use of OPAT requires integrated delivery of care for children who are assessed to be at low risk for development of complications from their infections and therapy and do not require skilled nursing care. Parents fulfill the role of a pediatric nurse in the hospital and should be capable of providing a focused, limited assessment of their child and communicating any concerning changes in the child's medical condition or concerns regarding adverse drug reactions or catheter or pump malfunction to the appropriate medical personnel. The antimicrobial agents, infusion equipment, and medical follow-up all should be designed

for the outpatient setting compatible with the training and resources available to parents or caregivers in the home. Outcomes of pediatric OPAT should be equivalent to or better than those achieved in an inpatient setting.

Antiviral Agents

239

Gail J. Harrison

The age of modern antiviral therapy began in the early 1950s, when methisazone, a derivative of the thiosemicarbazones (early antituberculosis compounds), was found also to have activity against vaccinia and variola viruses.^{39,40,239,487,584,619} In 1959, the first antiherpes compound, idoxuridine, was synthesized; in 1962, it was approved for the topical treatment of herpetic keratitis.^{140,323,474} Shortly thereafter, in 1964, trifluridine also was used to treat herpetic keratitis.^{324,325,611} Also in 1964, the first description of vidarabine as an antiviral agent active against herpes simplex virus (HSV) was published, and amantadine was shown to have activity against influenza virus.^{136,512} Two years later, amantadine was approved first for the prophylaxis and subsequently for the treatment of influenza A virus infection.⁵¹⁵ Shortly thereafter, in 1972, vidarabine was approved for the treatment of herpes encephalitis.⁶⁰⁷ The year 1972 also marked the first description of ribavirin as a broad-spectrum antiviral agent, with activity against both DNA and RNA viruses, and in 1985, the aerosolized form of the drug was approved for the treatment of respiratory syncytial virus (RSV) bronchiolitis.^{139,565} In 1977, acyclovir was reported to be a potent and selective inhibitor of the replication of both HSV and varicella-zoster virus (VZV) and boasted the added advantage of a favorable safety profile.^{138,165,550} Subsequently, several structural analogues of acyclovir led to the development of antiviral agents with expanded antiviral spectra, such as ganciclovir, and agents with more favorable bioavailability, such as with the prodrugs valacyclovir and valganciclovir.^{128,391} In the 1990s, the introduction of cidofovir, a broad-spectrum, long-lasting antiviral agent, and the neuraminidase inhibitors zanamivir and oseltamivir, which treat both influenza A and influenza B viruses, added new dimensions to antiviral therapy.^{84,125,261,358,540} In 2007, the oral antiviral agent maribavir, and in 2011, the oral antiviral agent letermavir, both with unique anti-cytomegalovirus (CMV)-specific activity, were granted US Food and Drug Administration (FDA) orphan drug fast track status, and the antivirals are now in phase III clinical trials in immunocompromised patients with or at risk for resistant CMV infections.⁶¹¹ Peramivir was the first intravenous antiviral for treatment of influenza A and B infection and was licensed by the FDA in 2014. The research now being conducted no doubt will expand our antiviral armamentarium to combat viruses that may be used as biologic weapons as well as to prevent the emergence of resistant viruses and spawn creative strategies such as multidrug therapy and targeted delivery systems.^{209,251}

Even though diseases caused by viruses (Box 239.1) now may be treated with a variety of antiviral agents, the close relationship between the viral replicative cycle and its host cell metabolism unfortunately has caused the development of safe and effective antiviral agents to lag behind the development of other antimicrobials, such as antibiotics

and antifungals. Clinically successful antiviral agents target and inhibit virus-specific functions while keeping cellular toxicity to a minimum. In addition, as a further testament to the codependency between viruses and host cells, some antiviral agents actually require cellular metabolism for antiviral activity, such as the terminal phosphorylation of acyclovir monophosphate to the active triphosphate form.

Antiviral agents can be categorized as virucidals, antiviral chemotherapeutic agents or drugs, and immunomodulators. Virucidal agents inactivate the virus on contact and include detergents, solvents, and ultraviolet light. These agents are not useful for treatment of human viral disease because healthy tissue also is destroyed. They may, however, be used to inactivate viruses on the surface of the skin or inanimate objects. Antiviral treatments that physically destroy both virus and the tissues infected or transformed by them include cryotherapy, laser therapy, and podophyllin and are used primarily to treat recalcitrant or life-threatening warts on mucocutaneous or laryngotracheal tissue. The host immune response also is important and in many cases essential for recovery from viral disease or even maintenance of a latent or inactivated state of the virus. Therefore successful antiviral treatment may necessitate relief from immunosuppression when it is feasible, such as for patients with Epstein-Barr virus (EBV)-induced lymphoproliferative disease who are undergoing cancer chemotherapy or organ transplantation. It also may include the use of biologic response modifiers, or immunomodulators, that manipulate the immune system to enhance its ability to contain viral infection. Examples of immunomodulators include immune globulin and monoclonal antibody preparations, cytokines such as interferons, and even novel approaches such as virus-specific cytotoxic T-cell lines designed to reconstitute host immunity.^{22,36} In addition, supportive treatments, including fluid resuscitation, blood product transfusions, mechanical ventilation, and extracorporeal membrane oxygenation, are important for serious viral disease.^{24,121} Finally, updated knowledge about specific antiviral therapy licensed for hepatitis viruses is reviewed in Chapters 47, 157, and 177, and antiretroviral therapy is reviewed in Chapter 192.

Antiviral chemotherapeutic agents usually inhibit virus-specific events (Fig. 239.1), such as adsorption or attachment to the host cell (pleconaril), penetration and uncoating of the viral genome (amantadine), viral gene expression and nucleic acid synthesis (acyclovir, ganciclovir), and even viral assembly of intact, infectious viral particles (interferons). Therefore antiviral agents exhibit their “antiviral effect” primarily while viral replication is active at the host cell level. If the antiviral compound is withdrawn or discontinued, viral replication resumes. Furthermore, the currently available antiviral agents do not appear to eliminate viruses that are latent or in other dormant or nonreplicative states. The goal

 Hepatitis C virus
 Acute and chronic hepatitis
 Ebola virus
 Ebola virus hemorrhagic fever

of antiviral therapy, for the most part, is to inhibit active viral replication to such a degree that the host immune response is able to contain or in some instances even to eliminate the infection.

Antiviral agents usually have a narrow range of activity that can be predicted by their molecular mechanism of action. For example, rimantadine and amantadine have high activity against the RNA-containing influenza A virus, limited activity against influenza B virus, and virtually no activity against the DNA herpesviruses,^{125,136} whereas acyclovir, a deoxyguanosine analogue that requires monophosphorylation by the viral enzyme thymidine kinase (TK) for activation, has significant activity against DNA viruses (HSV), which carry TK, but no activity against RNA viruses such as influenza virus. Viruses infecting a host also may become resistant to a specific agent to which they originally were susceptible, usually by induced or selected mutations. Resistance is therefore most likely to occur in viruses that infect the host with a high viral load and that have a high intrinsic viral mutation rate as well as in viruses that infect hosts who are exposed to selective drug pressure during chronic, low-dose, or repeated treatment with an antiviral agent.²⁷⁴ Both resistant and sensitive viruses are capable of causing serious disease, especially in an immunocompromised host. Currently, most antiviral agents are administered as single therapeutic agents. However, double and triple combination antiviral drug therapy, now a routine therapy in modern antiretroviral regimens, is also important in selected circumstances for treatment of other viral diseases in immunocompromised

hosts or where presence or emergence of drug-resistant viruses is likely.^{25,245,251,443,445} Combination strategy increases antiviral effectiveness, prevents the emergence of drug resistance, and allows the administration of lower, less toxic dosages.^{34,45,263,504,505}

ANTIVIRAL AGENTS ACTIVE AGAINST RNA VIRUSES

Table 239.1 provides a list of antiviral agents active against RNA viruses, including their clinical indications and usual dosages.

Amantadine and Rimantadine

Spectrum of Activity

Amantadine (1-adamantanamine hydrochloride) and rimantadine (α -methyl-1-adamantane methylamine hydrochloride) are tricyclic amines with specific activity against influenza A viruses (Fig. 239.2). Mean inhibitory concentrations of 0.1 to 0.4 $\mu\text{g/mL}$ for amantadine have been reported, and rimantadine is 4 to 10 times more active than amantadine against susceptible subtypes of influenza A virus.^{77,249,467} Amantadine also has in vitro activity against rubella virus, but efficacy was not confirmed in animal models.^{453,454,513,555} Much higher concentrations (10–50 $\mu\text{g/mL}$) appear to inhibit influenza B virus and parainfluenza viruses, but these high concentrations cannot be achieved safely in humans.⁵¹³ Research and development continue with designs of more

TABLE 239.1 Clinical Indications and Usual Treatment Dosages for Licensed Antiviral Agents Active Against RNA Viruses

Agent	Indication	Dosage
Amantadine	Influenza A	2.2–4.4 mg/kg/dose PO bid (max, 100–200 mg daily)
Rimantadine	Influenza A	2.5 mg/kg/dose PO bid (max 150 mg daily)
Oseltamivir	Influenza A and B	2 mg/kg/dose PO bid (max 150 mg daily)
Zanamivir	Influenza A and B	5 mg/dose inhaled bid
Ribavirin	Respiratory syncytial virus	6 g/300 mL inhaled daily in an 18-h period or 2–6 g/100 mL inhaled in a 2-h period tid
	Hepatitis C	600 mg PO bid (with interferon alfa)

adamantane-like inhibitors of the M2 proton channel against influenza A virus.^{157,467} The adamantanes also have significant activity against hepatitis C virus (HCV) and rhabdoviruses (vesicular stomatitis virus and rabies virus).^{527,534,612}

Mechanism of Action and Resistance

The mechanism of action of both amantadine and rimantadine against influenza A virus appears to be primarily inhibition of the ion channel

FIG. 239.2 Structure of amantadine and rimantadine.

function of the M2 protein in the membrane of the virus, possibly affecting two stages of viral replication: uncoating and, to a lesser extent, assembly.^{23,125,244,467} Amantadine and rimantadine resistance occurs when mutations cause an amino acid change in one of four critical sites (amino acids 26, 27, 30, and 31) in the transmembrane channel or domain of the M2 viral protein.³⁴³ Such mutations occur frequently and rapidly during therapy because approximately 30% of adults and children who receive amantadine or rimantadine therapy for at least 5 days shed resistant influenza virus.^{247,250} These resistant strains are genetically stable, may be transmitted to close contacts, and can produce disease.^{46,246,247,632} Immunocompromised patients may shed drug-resistant influenza viruses for prolonged periods, and resistant strains can persist even after drug administration has been discontinued.³⁴³ However, debate has begun among experts concerning whether patients in whom a resistant strain is identified should be isolated until viral shedding has ceased.²³⁴ Adamantane-resistant strains of influenza A subtype H3N2 and subtype H1N12009 have produced community outbreaks and epidemics.^{46,246,247,632} Some strains of highly pathogenic A(H5N1) avian influenza are susceptible to adamantanes, but most strains of A(H5N1) should be considered resistant.²⁹⁸ Strains of influenza A virus resistant to amantadine also are resistant to rimantadine, and vice versa, but they are usually susceptible to ribavirin and neuraminidase inhibitors. The mechanism of action against rabies virus appears to be by inhibition of later steps in replication, probably at the level of uncoating, when the virus is released into the intracytoplasmic compartment of infected cells.⁵⁶⁷

Pharmacokinetics

Amantadine is absorbed rapidly and nearly completely after oral administration, with peak plasma concentrations of 0.5 to 0.8 µg/mL attained within 2 hours of administration.^{56,255} It is excreted almost unchanged in urine. Nasal and salivary secretions also contain high levels of amantadine, and the drug is present in cerebrospinal fluid (CSF) as well at approximately half the plasma level. Dose reductions, adjusted according to creatinine clearance, are required in patients with renal insufficiency and renal failure.^{285,504,621} Rimantadine, on the other hand, is more slowly absorbed than amantadine, with peak plasma levels of 0.4 to 0.6 µg/mL achieved within 2 to 4 hours of administration.^{15,16,255,433} Rimantadine is also present in high concentration in nasal secretions. It is excreted in urine, but only after extensive metabolism by the liver. Dose reduction is therefore recommended in patients with renal or hepatic disease.^{86,613} Hemodialysis does not appear to clear either drug, so supplemental doses usually are not recommended after dialysis.⁵⁴⁶ When they are administered to chronically ill, institutionalized older adult patients, dosages also may need to be adjusted.^{424,461} In addition, aerosolized forms of amantadine and rimantadine have been evaluated in human volunteers.^{253,259}

Clinical Indications, Dosage, and Adverse Effects

Clinical indications. Amantadine and rimantadine are equally effective for the treatment of disease caused by susceptible subtypes of influenza A virus.^{125,343,613} If they are administered within the first 48 hours of symptoms, both agents significantly reduce the signs and symptoms of influenza in both adults and children by significantly shortening the duration of fever and respiratory and systemic symptoms by 1 day.^{125,142,375,585,614,625} The duration and amount of viral shedding from the nasopharyngeal tract also are decreased, and otologic complications

may be reduced.¹⁵² Both agents are effective for prophylaxis against influenza A virus infection and disease, with approximately 50% overall effectiveness in preventing infection with the virus and approximately 60% to 70% overall effectiveness (up to 90% in some studies) in preventing clinical disease and, in individuals with breakthrough clinical disease, in reducing the severity of the disease.* The spontaneous emergence of resistant strains during rimantadine or amantadine therapy and subsequent transmission of these resistant strains may lessen the effectiveness of prophylaxis in some families and nursing homes.^{247,398} Amantadine and rimantadine are both available as tablets (100 mg) and syrup (50 mg/5 mL) for oral administration.

Emergence of resistance to adamantanes has limited the use of amantadine and rimantadine as single agents for influenza treatment. Since 2005, all circulating H3N2 subtypes of influenza A virus have been resistant to amantadine and rimantadine. Also resistant to adamantanes is the 2009 pandemic subtype influenza A(H1N1)pdm2009, which replaced the previously susceptible seasonal H1N1 subtype when it emerged. Influenza B is intrinsically resistant to the adamantanes. Amantadine has also been included in treatment protocols for patients with rabies encephalitis.⁶¹²

Dosage.

The usual dose of amantadine for children is 4.4 to 8.8 mg/kg per day divided twice daily (many experts recommend 5 mg/kg per day), with a maximal recommended daily dose of 200 mg. The usual dose of rimantadine for children is 5 mg/kg per day divided twice daily, with a maximal recommended daily dose of 150 mg.^{15,234,433,613} Older children and adolescents may take the usual adult dose for each drug, which is 200 mg/day given once daily or, for better tolerance, divided into two 100-mg doses daily.¹⁵ Older adult patients should receive 100 mg daily or less if renal insufficiency is present. To be effective, these agents should be given as soon as possible after the onset of symptoms.^{126,125} The duration of treatment of established influenza should be 3 to 7 days, or at least 2 days after the cessation of systemic signs and symptoms.¹²⁵ Prevention of influenza is accomplished best through annual vaccination; however, rimantadine and amantadine may be used to prevent or to lessen influenza symptoms in both adults and children.^{112,125,127} Prophylaxis should be administered during the period of risk, whether exposure is in the family, community, or nosocomial setting.²⁰² In general, prophylaxis should continue for at least 10 days after a known exposure occurs in an unprotected individual.²⁰² For patients who receive the combination of inactivated vaccine and oral prophylaxis, rimantadine or amantadine should be continued for at least 2 to 4 weeks after vaccination, when maximal antibody response from the vaccine is expected to occur. For patients who are at high risk but did not receive the vaccine, oral prophylaxis should be continued for as long as the period of risk is anticipated and may be extended to the end of the community's influenza season. Doses of both drugs should be adjusted for patients with renal disease, and doses of rimantadine should be adjusted for patients with hepatic disease.^{86,285,504,613} Prolonged treatment may be associated with side effects, especially in older adults.⁴⁶¹ If side effects occur, the daily dose may be reduced to 100 mg and still be effective in most cases. The emergence of resistant strains during the period of drug administration may lessen the effectiveness of prophylaxis in some patients.^{247,398} Combination with aerosolized ribavirin or the neuraminidase inhibitors may enhance the antiviral effect of amantadine or rimantadine against influenza A virus.^{34,245,284,444,526}

An amantadine dose of 200 mg daily, combined with therapeutic coma, ketamine infusion, and management of cerebral vasospasms, known as the Milwaukee Protocol for Rabies, has been used to treat rabies encephalitis.⁶¹² However, recent critical appraisal of this protocol has not substantiated its efficacy for treatment of rabies encephalitis.⁶³⁰

Amantadine also has applications for noninfectious conditions. For example, high-dose amantadine has been used to treat dyskinesia in Parkinson disease.³⁴⁷ A recent case report showed that amantadine may be useful in the treatment of unresponsive wakefulness syndromes, such as persistent vegetative state, due to central nervous system (CNS) disease.³⁶⁸

Adverse effects. The adverse effects of both amantadine and rimantadine include CNS effects such as anxiety, depression, insomnia, dizziness, and impaired concentration; in children, these side effects appear to be rare, but they may be manifested as behavioral changes.^{112,125,150,542} Rimantadine reportedly has fewer CNS side effects than amantadine.^{125,150,254,418} Hallucinations, tremors, and seizures also may occur, especially in patients with renal failure who have high plasma levels of amantadine. In addition, rare cases of coma and fatal cardiac dysrhythmia have been reported.^{468,504} A prudent procedure is to administer amantadine and rimantadine with caution to individuals being treated for seizures or neuropsychiatric disorders or to patients also receiving other medications that affect the nervous system, such as antihistamines.⁴¹⁸ Furthermore, institutionalized older adults may have increased plasma levels and experience side effects more often than younger patients.⁴⁶¹ On occasion, gastrointestinal symptoms such as nausea and vomiting may accompany the oral administration of these agents in all age groups. Most reported adverse effects of these two agents have been reversible, with significant long-term complications being exceedingly rare. Of note, amantadine also is used to treat parkinsonism and drug-induced extrapyramidal reactions.⁵¹⁵

Neuraminidase Inhibitors (Zanamivir, Oseltamivir, Peramivir, and Laninamivir)

Spectrum of Activity

Zanamivir (5-[acetylamino]-4-[(aminoiminomethyl)-amino]-2,6-anhydro-3,4,5-trideoxy-D-glycero-D-galacto-non-2-enoic acid) and oseltamivir ([3R,4R,5S]-4-acetylamino-5-amino-3-[1-ethylpropoxy]-1-cyclohexene-1-carboxylic acid ethyl ester phosphate [1:1]) are analogues of N-acetylneuraminic acid, the cell surface receptor for influenza viruses, and were designed to inhibit the viral neuraminidase of influenza viruses (Fig. 239.3). Oral oseltamivir and inhaled zanamivir are licensed in the United States. The cyclopentane peramivir ([1S,2S,3S,4R]-3-[(1S)-1-acetamido-2-ethyl-butyl]-4-(diaminomethylideneamino)-2-hydroxy-cyclopentane-1-carboxylic acid) and laninamivir ([4S,5R,6R]-acetamido-4-carbamimidamido-6-[(1R,2R)-3-hydroxy-2-methoxypropyl]-5-6-dihydro-4H-pyran-2-carboxylic acid) are newer neuraminidase inhibitors currently in clinical trials in the United States.

These four agents are potent and specific inhibitors of the neuraminidases of influenza A (seasonal H3N2, seasonal H1N1, H1N1pdm2009, and avian influenza viruses, including highly pathogenic H5N1 and H9N2) and influenza B viruses. Up to 90% of tested strains are inhibited at concentrations of 0.05 to 100 $\mu\text{mol/L}$.^{221,334,389}

FIG. 239.3 Structure of the neuraminidase inhibitors oseltamivir and zanamivir.

*References 125, 143, 150, 202, 305, 306, 425, 449, 496, 602, 633.

Peramivir has also shown efficacy for the treatment of influenza A and B, especially H1N1pdm2009, in at least four efficacy trials.⁵³ Peramivir, intravenous form, was first licensed in Japan and Korea in 2010, and in 2014 was approved by the FDA. Peramivir was first authorized for emergency use in the United States and other countries for treatment of adults and children with severe influenza during the 2009 H1N1 pandemic. It also was administered through emergency investigational new drug regulations^{263,280} and appeared to be well tolerated and associated with recovery.²⁶³ However, because peramivir under emergency use authorization was limited to critically ill patients for whom other therapy had failed or in whom oral drug absorption was unreliable or inhalation drug not feasible, the efficacy and safety of peramivir could not be adequately assessed. Peramivir intravenous preparation is now approved by the FDA for treatment of adults with symptomatic but uncomplicated influenza, who have had symptoms for less than 2 days, and shows similar efficacy and safety profiles compared with oral oseltamivir.^{434,604}

Long-acting inhaled laninamivir octanoate is a new neuraminidase inhibitor, with activity against highly pathogenic avian influenza virus H5N1 in addition to influenza A (seasonal H3N2, seasonal H1N1, and H1N1pdm2009) and influenza B.^{177,268,515,523} Laninamivir is licensed and available in Japan and in phase III clinical trials in the United States.^{299,535,625} Influenza A (AH5N1, AH1N1) and B virus strains with reduced susceptibility to neuraminidase inhibitors (oseltamivir, zanamivir, and peramivir) have also been detected in hospitalized patients and community-acquired cases of influenza.^{35,177,268,281,294-297,299,556,568}

Because influenza virus changes seasonally and antiviral resistance may evolve or emerge suddenly, any statements on presumed spectrum of antiviral activity of any neuraminidase inhibitor should be taken in the context of ongoing viral surveillance.^{177,294,303,515,528}

These compounds also are capable of inhibiting neuraminidases from other pathogens and mammalian cells, but only at extremely high concentrations.

Mechanism of Action and Resistance

Neuraminidase permits influenza virus to penetrate through the mucoproteins present in respiratory secretions to the surfaces of cells, and inhibition of this enzyme prevents viral access and infection of cells. Neuraminidase also destroys receptors recognized by viral hemagglutinin and is therefore necessary for optimal release of influenza virus particles from infected cells. Inhibition prevents cell-to-cell spread of virus within the respiratory tract and lessens the intensity of the initial infection.^{116,125,334,437,589} Mutations that induce amino acid changes in viral neuraminidase alter enzyme stability or activity, mutations in hemagglutinin produce a reduced affinity for cell receptors, and mutations in both produce resistant influenza viruses.^{125,225-228} Cross-resistance to both zanamivir and oseltamivir, as well as to oseltamivir and peramivir, also can occur, especially if the mutation is in the hemagglutinin portion.⁴¹³ Resistance occurs either by spontaneous mutation or by selection during antiviral treatment and has been documented by *in vitro* passage of the virus in increasing concentrations of the agents, in patients receiving these antiviral agents, and in newly emerged strains that acquire a change in neuraminidase through mutation or reassortment. In 2007, influenza A(H1N1) seasonal acquired a change in neuraminidase, designated H275Y, that resulted in oseltamivir resistance, but zanamivir susceptibility was retained. In 2009, oseltamivir-susceptible influenza A(H1N1)pdm2009 emerged, replacing the oseltamivir-resistant seasonal H1N1. Beginning in 2009, individual cases of oseltamivir resistance, usually in immunocompromised patients receiving treatment, as well as community clusters of oseltamivir-resistant influenza A(H1N1)pdm2009, began to be detected.^{92,158} Sporadic oseltamivir resistance has also been detected in avian influenza A(H5N1). Clinical trials of oral oseltamivir for the treatment of naturally occurring influenza detected resistance in 1% to 2% of posttreatment isolates from adults and adolescents and in 5% to 8% of isolates from younger children.^{125,227,285,628} Currently, most seasonal H1N1 strains circulating in 2008–2009 were resistant to oseltamivir, and the overall occurrence of influenza A H1N1 subtypes resistant to oseltamivir is estimated at a rate of 2.6%, with an association between oseltamivir resistance and pneumonia in four clinical studies.^{35,246,296,299,576}

Peramivir resistance has also been documented in both influenza A, including pandemic A(H1N1)pdm2009, and influenza B.⁴⁵⁸ A point mutation at H273Y in one influenza B isolate from a human patient conferred double resistance to both oseltamivir and peramivir.²⁶⁸ Most peramivir- and oseltamivir-resistant influenza strains remain susceptible to zanamivir at this time.

Zanamivir resistance appears rare, documented in case reports of either influenza A or B virus infection in patients who were usually immunocompromised hosts receiving antiviral medications for prolonged periods.^{224,225,252,256,260,420,576} Large randomized trials of healthy individuals have not documented zanamivir resistance, but individualized case reports and small case series have shown that zanamivir resistance has emerged.^{225,252,256,260,420} In one study from Australia, analysis of 391 influenza A(H1N1) seasonal isolates documented zanamivir resistance in 9 (2.3%) isolates.²⁹⁷ Influenza B viruses with mutations in the neuraminidase active site conferring resistance to oseltamivir, peramivir, and zanamivir have been reported from several geographic sites.^{177,268,515,528} Overall, there are currently at least 50 different documented amino acid substitutions that have produced mutations conferring reduced antiviral susceptibility to oseltamivir, zanamivir, peramivir, or laninamivir in influenza A and B viruses.^{442,446} Preliminary evidence suggested that some mutant resistant strains may have reduced infectivity or virulence compared with susceptible strains,⁵⁷¹ but resistant strains have caused outbreaks and epidemics.²⁴⁶ Therefore difference in influenza virulence cannot be predicted by the antiviral susceptibility pattern of the strain.

Pharmacokinetics

Zanamivir is administered as an inhaled dry powder and is deposited in the oropharynx and, to a lesser extent, in the tracheobronchial tree and lungs.¹²⁵ Approximately 4% to 17% of inhaled drug is absorbed systemically, and levels of 17 to 142 ng/mL can be detected in serum 1 to 2 hours after administration of a typical inhaled dose of 10 mg in adults.⁸⁸ Serum levels in pediatric patients who received an inhaled dose were extremely low (<10 ng/mL) or undetectable, which may be related to the ability of the patient to cooperate with the inhaled drug delivery system. The oral bioavailability of zanamivir is extremely low, with less than 5% of the administered dose absorbed, and therefore it is not administered in this form. Intravenous and intramuscular preparations of zanamivir also have been tested in clinical trials, but these forms are not available clinically at this time.^{85,88,199,246} Intravenous zanamivir provides a sustained antiviral effect.¹⁹⁴ It also penetrates lung tissue. Zanamivir administered intravenously at doses of 100 mg, 200 mg, and 600 mg provides concentrations in epithelial lung fluid 12 hours after dosing of 74, 146, and 419 ng/mL, respectively.⁵²³ In contrast, inhaled zanamivir concentrations provide much higher levels of 396 to 891 ng/mL to the respiratory tract. Zanamivir is not metabolized, and approximately 90% of zanamivir is excreted unchanged in urine.⁸⁸

Oseltamivir, in contrast, has good oral bioavailability. The prodrug compound oseltamivir phosphate is metabolized by hepatic esterases to the parent active compound oseltamivir carboxylate.¹²⁵ Approximately 75% to 80% of the administered dose is absorbed, and peak plasma concentrations are reached within 3 to 4 hours but may be delayed, but not reduced, if the drug is given with food. A typical 75-mg dose will provide plasma concentrations of 0.3 to 0.5 µg/mL. Both the prodrug and the active form are eliminated unchanged through the kidneys, and dosages should be adjusted for patients with renal insufficiency or renal failure. Whether the drug dosage should be adjusted for patients with hepatic disease or liver failure is unclear from the available evidence. Information from a small number of pediatric patients suggests that the drug may be eliminated faster in younger children. Geriatric patients, however, appear to metabolize the drug similarly to young adults. Oseltamivir phosphate and oseltamivir carboxylate both may be found in breast milk, but often in concentrations lower than considered therapeutic for infants.²²²

Peramivir administered orally in doses ranging from 100 to 800 mg daily is not well absorbed and produces only modest antiviral effect.³⁸ Peramivir has been administered intravenously in doses of 200, 400, and 600 mg daily, or approximately 4 to 10 mg/kg once daily.³⁰¹ Plasma concentration of approximately 20 ng/mL within 24 hours of infusion has been documented, which is far in excess of the reported half maximal

inhibitory concentration (IC₅₀) of peramivir against susceptible influenza strains. Pediatric dosing for peramivir suggests that 10 mg/kg daily produces adequate plasma levels and good antiviral effect with few adverse effects.⁵²⁴ Pregnant or postpartum women may require higher doses on the basis of limited pharmacokinetic studies that have demonstrated increased plasma volume, increased volume of distribution of peramivir, and shorter half-life.¹¹¹ The half-life of peramivir varies between 7 and 20 hours in patients with normal renal function. Peramivir is excreted in the urine as the unchanged form, and dosage adjustments are needed in renal impairment. Patients with proven influenza infection show antiviral effects, with decreased viral shedding between days 2 and 6 of treatment (7–20%) and with clinical improvement and recovery.⁵²⁴

Laninamivir octanoate is the prodrug of the active compound laninamivir. It is administered as a single inhalation of either 20 mg or 40 mg to treat influenza infection. It is retained in the tissues and eliminated from the body very slowly, with a plasma half-life of 2 hours and lasting at least 3 days. Urinary excretion appears to occur. Clinical trials show that one inhalation of laninamivir is an effective and well-tolerated treatment for children and adults with seasonal influenza, including oseltamivir-sensitive and oseltamivir-resistant influenza A(H1N1) virus infection.^{523,599}

Clinical Indications, Dosage, and Adverse Effects

Clinical indications. Zanamivir and oseltamivir have been shown to be effective in treating both influenza A and influenza B infection.^{84,261,316,399,598,599} However, susceptibility of type B and H5N1 and H1N1 subtypes of type A influenza may be reduced for oseltamivir.⁵⁶⁷ When they are administered within the first 2 days of illness, they provide relief from symptoms up to 1.5 days earlier than placebo does and reduce the quantity and duration of viral shedding.* In some studies, the frequency of secondary complications, such as sinusitis, bronchitis, and otitis media with effusion (but not pneumonia), also was reduced.^{125,594} Both antiviral agents are effective for the prophylaxis of influenza A and influenza B infection in both adults and children in family, community, transplant recipient, and nursing home situations.³⁰³ They appear to be 30% to 50% effective in preventing viral infection and 64% to 84% effective in preventing disease.^{125,252,258,402,426,594} However, up to 89% efficacy in preventing disease in families has been reported, and in older adult patients in nursing homes, 92% of cases of influenza may be prevented if the agents are administered to those who also have received influenza vaccine.^{125,252,402} Oseltamivir may be administered to a patient of any age to treat influenza.

Peramivir may be administered intravenously, under investigational or emergency investigational new drug or clinical trials, to patients unable to tolerate oral oseltamivir or inhaled zanamivir.^{380,496} The temporary emergency use authorization for peramivir for treatment of 2009 H1N1 influenza, granted by the FDA and managed through the Centers for Disease Control and Prevention (CDC), terminated in June 2010.^{53,263} On the basis of results of clinical trials and experience with the emergency use authorization, 300- to 600-mg doses of peramivir appear to be effective for treatment of high-risk patients infected with susceptible influenza A or B virus strains.^{53,263,346} Peramivir probably should not be used to treat patients with oseltamivir-resistant influenza infection (H275Y mutation), patients with mutations of neuraminidase E119D or R292K (which confer peramivir resistance), or patients suspected of having influenza caused by zanamivir resistance because it is likely not to be effective.

Laninamivir may be administered in some countries as a single inhalation to treat influenza A H1N1 and H5N1 infections in adults and children. A dose of laninamivir, 20 to 40 mg, administered in a single inhalation, is retained in the respiratory tissues for a prolonged time, providing very high levels, in excess of the IC₅₀ of susceptible influenza strains. This high level may reduce the risk for emergence of resistant strains. Inhaled or intranasal laninamivir also enters the plasma, and renal excretion correlates with creatinine clearance. Pharmacokinetic studies suggest that dose adjustment may be necessary only in severe renal insufficiency.^{301,599}

Intravenous zanamivir, which remains investigational at this time, appears effective in treating high-risk, critically ill patients, including immunocompromised patients, with oseltamivir- or peramivir-resistant influenza A infection.^{158,194,208,303,458}

Dosage. Zanamivir is administered by oral inhalation with an inhalation device provided with the product. Each inhalation dose is 5 mg, and two inhalations twice daily for 5 days is the usual recommended dosage for all age groups. Use of this drug and device is dependent on the understanding and cooperation of the patient; therefore it is not indicated for use in children younger than 7 years and may be of limited use in older children and adults who are unable to cooperate with the delivery system. No reduction in dosage is needed for patients with impaired renal function because very little of the inhaled drug is absorbed systemically.

Zanamivir has also been administered by nebulizer at a dosage of 16 to 32 mg (usually 24 mg) in 1 to 2 mL of sterile water every 6 hours for 5 to 10 days.²²⁴

Zanamivir has been administered intravenously in doses of 600 mg at a constant rate during 30 minutes, every 12 hours for 5 days, under investigational, compassionate use to individual patients and currently is being evaluated in clinical trials (<https://clinicaltrials.gov>).^{149,158,243} Pediatric dosing in the clinical trials is weight based and age adjusted. A dose of 4 to 10 mg/kg per dose every 12 hours has been evaluated.¹⁵⁷ Younger children appear to require higher doses; children who weigh less than 11 kg may be given up to 24 mg per dose if renal function is normal. Some institutions have administered up to 16 to 24 mg/kg per dose every 12 hours. All trials agree that a maximum of 600 mg/dose should be given twice daily, and this maximum dose should be used for children who are older than 13 years or weigh more than 37 kg and have normal renal function. Doses should be adjusted in renal impairment according to creatinine clearance.

Oseltamivir is administered orally and is available in 75-mg capsules and a 12-mg/mL suspension. The usual adult dosage is 75 mg twice daily for treatment and once or twice daily for as long as 6 weeks for prophylaxis. The pediatric dose is 2 mg/kg per dose given twice daily (4 mg/kg per day divided twice daily).¹²⁵ Double dosing of oral oseltamivir (up to 150 mg twice daily for adults and older children) was recommended for some patients during the 2009 H1N1 influenza A pandemic and may be used for treatment of severe seasonal or pandemic influenza or influenza caused by a strain thought to have reduced susceptibility to oseltamivir.¹¹¹

Peramivir has been administered intravenously to adults in doses between 300 and 600 mg once daily, during a 60-minute infusion.^{544,626} Weight-based dosing suggests a once-daily dose of approximately 4 to 10 mg/kg. Duration of treatment is recommended for 5 to 10 days.^{301,302} Pediatric dosing, for ages 3 months to 15 years, has been studied. A once-daily dose of 10 mg/kg, with a maximum daily dose of 600 mg, appears to be clinically and virologically effective and safe in infants and children with influenza.^{524,564} Neonates should be dosed at 6 mg/kg daily and infants at 8 to 10 mg/kg daily, according to FDA guidance (<https://www.fda.gov>). Dosage adjustments are needed in renal impairment. Patients with severe or end-stage renal disease should probably receive 100 mg daily and after each dialysis because peramivir is cleared by dialysis (<https://www.fda.gov>).

The dose of laninamivir is 20 to 40 mg, administered in a single inhalation to treat the entire illness. Dosage adjustments are necessary only in severe renal impairment.^{301,563,599}

Adverse effects. Both neuraminidase inhibitors are generally well tolerated, with few if any serious adverse effects observed in clinical trials. Zanamivir inhalation, however, may produce local irritation or bronchospasm in some patients. Oseltamivir has been associated with nausea and vomiting, which may be lessened by administration of the drug with food, and, rarely, psychosis and other psychiatric disorders, and renal, metabolic and cardiac reactions such as bradycardia and QT prolongation.^{125,238} The most commonly observed side effect of inhaled laninamivir is gastrointestinal. The most common side effects of intravenous peramivir are nausea, vomiting, diarrhea, and neutropenia. Rarely, skin reactions and anaphylaxis have occurred with peramivir administration. Intravenous zanamivir appears well tolerated on the basis of limited clinical experience at this time.

FIG. 239.4 Structure of ribavirin.

Ribavirin

Spectrum of Activity

Ribavirin (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide) is a synthetic guanosine analogue with broad-spectrum antiviral activity (Fig. 239.4).⁵³⁶ It inhibits the *in vitro* replication of a wide variety of RNA viruses, including orthomyxoviruses, such as influenza A and B viruses; paramyxoviruses, such as RSV, parainfluenza viruses, and measles virus; arenaviruses, such as Lassa fever virus; bunyaviruses, which cause viral encephalitis; togaviruses, such as HCV; enteroviruses, such as enterovirus 71, polioviruses, and coxsackie B virus; rabies virus; and retroviruses, including human immunodeficiency virus (HIV) type 1.^{175,289,332,359,361,372,455,525,612} Also inhibited by ribavirin are many DNA viruses, such as adenoviruses, hepatitis A virus, CMV, and poxviruses (e.g., vaccinia virus).¹⁵¹ It inhibits most orthomyxoviruses and paramyxoviruses at concentrations of 3 to 10 μg/mL and Lassa fever virus at 4 to 40 μmol/L.²⁹² Because most of its clinical use has been for the treatment of RNA viruses, ribavirin is included in this section of the chapter.

Mechanism of Action and Resistance

Ribavirin most likely exerts its antiviral effects by altering the cellular nucleotide pools and by interfering with viral mRNA formation.^{76,175,558} The compound is phosphorylated by host cell enzymes to monophosphate, diphosphate, and triphosphate active forms, each with specific antiviral actions.⁵⁷² For example, ribavirin monophosphate competitively interferes with the synthesis of guanosine triphosphate and, subsequently, with viral nucleic acid synthesis. Ribavirin triphosphate inhibits the RNA polymerase of influenza virus and also interferes with the capping of its viral mRNA.^{175,332,455,609,620} In addition, the diphosphate and triphosphate forms of ribavirin appear to inhibit the reverse transcriptase activity of HIV-1.¹⁸² The mechanism of action of ribavirin against HCV and other viruses, however, is not well understood. Ribavirin also exerts an effect on the host immune system by inhibiting mast cell secretory responses and diminishing immunoglobulin E (IgE) responses.⁴⁸⁸ Antiviral resistance is not well characterized and appears to be a rare occurrence. No ribavirin-resistant RSV isolates have been identified during clinical trials, and information is scant regarding the resistance of other viruses to ribavirin.^{236,383,509}

Pharmacokinetics

Ribavirin can be administered by aerosol, orally, and intravenously. Aerosol administration of ribavirin with a small-particle aerosol generator delivers very high concentrations (>1000 μg/mL) of the drug to the respiratory tract.³⁴⁵ Aerosolized drug also is absorbed systemically, and peak plasma levels after 8 hours of continuous aerosol administration range from 0.5 to 2.2 μg/mL; after 20 hours, they reach 0.8 to 3.3 μg/mL. After oral administration, bioavailability is 33% to 45%, and peak plasma levels of 1.3 to 3.2 μg/mL have been observed 1 to 2 hours after administration. Intravenous administration of ribavirin produces 10-fold higher plasma levels in less than 1 hour than after the administration of equivalent doses by different routes.⁴⁵⁹ Higher doses used to treat Lassa fever produce plasma levels of up to 24 μg/mL. Ribavirin also crosses the blood-brain barrier and is present in CSF at approximately

70% of the plasma level.^{122,287} The drug is metabolized by the liver, and approximately 40% of the dose is excreted by the kidneys.⁴⁵⁹ The triphosphate form also concentrates in erythrocytes at an erythrocyte-to-plasma ratio of 40:1 and is slowly eliminated with a half-life of 40 days or longer. Hemodialysis and hemofiltration do not remove significant amounts of ribavirin from the body.³⁵⁰

Clinical Indications, Dosage, and Adverse Effects

Clinical indications. Ribavirin aerosol is licensed for the treatment of RSV bronchiolitis and pneumonia in children.²³³ Treatment shortens the duration of viral shedding and improves the fever, respiratory rate, arterial oxygen saturation, and lower respiratory tract signs on physical examination in severely ill patients who receive the antiviral agent early in the course of their illness.*

No clear benefit has been observed in otherwise healthy, low-risk patients with mild disease or in those who receive treatment late in the course of the disease. Studies of infants receiving mechanical ventilation have reported conflicting results in clinical benefit.^{410,422,537} However, despite numerous clinical studies, indications for treatment remain controversial because efficacy has not been documented convincingly in all studies and the benefits observed generally have been mild and difficult to quantitate objectively.²³³ Nonetheless, because antiviral treatment clearly appeared to provide benefit to some children, in 1996, the American Academy of Pediatrics recommended that ribavirin be considered for the treatment of hospitalized infants and children with severe lower respiratory tract infection caused by RSV. Currently, the American Academy of Pediatrics recommends that inhaled ribavirin may be considered for use in selected, high-risk patients with documented, potentially life-threatening RSV infection.¹² From 1996 to 2015, prescription of inhaled ribavirin for bronchiolitis in otherwise healthy infants hospitalized with bronchiolitis has declined, and most pediatric infectious diseases specialists are reserving the antiviral for use in seriously or critically ill and high-risk infants and children.^{41,87} Use of inhaled, oral, and intravenous ribavirin in allogeneic hematopoietic stem cell transplant recipients with RSV and other respiratory viruses has continued, with case series supporting clinical benefit in these high-risk patients, with few serious side effects.^{96,219,229,390,520}

Patients thought to potentially benefit the most from inhaled ribavirin treatment are those younger than 6 weeks; those with chronic illnesses, such as congenital heart disease and chronic lung disease; premature infants; immunosuppressed children with primary immune disorders or those undergoing allogeneic hematopoietic stem cell marrow or solid-organ transplantation; and those with neurologic or neuromuscular disorders.^{520,521} Treatment with ribavirin also appears to decrease nasopharyngeal secretion of RSV-specific IgE and IgA responses.⁴⁹⁴ Long-term follow-up of treated patients suggests no adverse effects but possible improvement in pulmonary function.^{265,313,379} Treatment may benefit immunocompromised children who have serious or prolonged RSV infection, such as those with congenital severe combined immunodeficiency.⁴⁰⁵ Aerosolized, oral, or intravenous ribavirin, especially combined with intravenous immune globulin or RSV hyperimmune globulin, also may be of benefit to bone marrow transplant recipients and solid-organ transplant recipients with RSV lower tract disease.^{135,213,379,382,423,606} Intravenous or oral administration appears less costly than aerosolized treatments.^{135,213,423} Anecdotal reports and case series suggest that early administration of inhaled or oral ribavirin, with or without palivizumab, to immunocompromised patients with cancer or transplant recipients, during early upper respiratory tract disease, may be more efficacious than supportive care alone in preventing progression to lower tract disease or pneumonia.^{96,170,405,520} Some centers have used oral ribavirin therapy for RSV infection, instead of inhaled or intravenous administration. Small studies and case series have shown similar therapeutic outcomes between oral and inhaled ribavirin therapy for RSV infection and lower respiratory tract disease after hematopoietic stem cell and solid-organ transplantation.^{219,229,371,390,462} Laboratory confirmation of RSV infection by viral culture or rapid diagnostic tests that detect viral antigen in respiratory secretions is recommended for all patients before treatment with ribavirin is initiated or continued beyond 12 to 24 hours.

*References 223, 235, 265, 313, 410, 422, 475, 532, 535, 605.

Ribavirin also is licensed in capsule form for the treatment of chronic hepatitis caused by HCV, and in combination with interferon alfa, it produces a sustained decrease in HCV RNA levels, improvement in systemic symptoms such as fatigue, reduction in transaminases, and improvement in liver histologic features. These clinical benefits have been observed during initial treatment in previously untreated patients, in individuals initially unresponsive to interferon alone, and in patients treated for relapse.^{55,58,137,147,198,286,404,481}

Treatment with high doses of orally or intravenously administered ribavirin significantly reduces mortality rates in patients with Lassa fever.^{71,311,403} Ribavirin also appears to benefit patients suffering from other hemorrhagic fever syndromes, including Argentine, Sabiá, Bolivian, and Crimean-Congo hemorrhagic fevers, as well as those who have hemorrhagic fever with renal failure syndrome.^{172,185,290,291,333} Ribavirin has also been used to treat La Crosse encephalitis, but clinical trials have not shown a clear therapeutic benefit.⁴⁰⁶ In addition, ribavirin may benefit patients with other causes of viral encephalitis, including rabies, but clinical trials have not been performed, and proven benefit is lacking.⁸⁹ Oral ribavirin also may be of benefit prophylactically in individuals who are exposed to hemorrhagic fever syndromes, including Lassa fever.²⁸² Treatment of hantavirus pulmonary syndrome with intravenously administered ribavirin is being evaluated in clinical trials.

Ribavirin may benefit individuals with influenza A or B virus infection. In one randomized study of young adults suffering from influenza, aerosol treatment significantly reduced fever, systemic signs and symptoms, and virus titer in respiratory secretions.⁵³⁶ Another study showed clinical benefit with high-dose oral ribavirin, but other studies have not confirmed a measurable clinical benefit or virologic response consistently with aerosolized or oral ribavirin.^{50,344,512,536,554} Intravenous ribavirin also has been used anecdotally to treat serious, life-threatening influenza.^{257,477} Early treatment with aerosolized or intravenous ribavirin in bone marrow and stem cell transplant recipients infected with parainfluenza virus may help prevent progression to lower tract disease and pneumonia or treat viremia and myocarditis, but controlled trials documenting efficacy and effect on overall mortality rates have not been published.^{166,257,320,603} Ribavirin also has been used to treat measles pneumonia in immunocompetent and immunocompromised patients, with clinical benefit reported in some.^{191,230,321} Ribavirin has also been included in treatment protocols for patients with rabies encephalitis, with unproven benefit.^{387,612}

Clinical benefit, but not cure, also has been documented in case reports of children with subacute sclerosing panencephalitis caused by measles virus.^{286,287,432,532} In these reports, repeated courses of large doses of ribavirin administered intravenously, combined with interferon alfa, provided serum and CSF levels that exceeded the minimal inhibitory concentrations needed to inhibit the virus *in vitro* and improved or stabilized seizures and neurologic status in treated patients.²⁸⁷ Case reports and small series using ribavirin to treat serious adenoviral disease, including pneumonia and disseminated adenoviral disease, have been published, but no controlled trials documenting clinical benefit have been published.^{32,64,94,206,397,430} Despite documented antiretroviral activity, treatment of HIV-infected patients with oral ribavirin has not shown clinical, virologic, or immunologic benefits consistently.^{122,182,314} Recently in 2017, there have been published reports of use of intravenous and oral ribavirin to treat severe fever with thrombocytopenia syndrome (SFTS), an emerging, summertime, severe and often fatal tick-borne disease in China, Japan, and Korea.³⁰⁰

Dosage. A number of different dosages and routes of administration have been used to administer ribavirin to a variety of patients experiencing various infections. In normal and immunocompromised patients of all ages, the usual dosage of ribavirin, when it is administered topically by aerosol to the respiratory tract for treatment of influenza and lower respiratory tract disease caused by RSV, parainfluenza virus, and measles virus, is 6 g of drug reconstituted in a final volume of 300 mL of sterile water (final concentration, 20 mg/mL); a small-particle aerosol generator (SPAG-2 unit) is used to administer the drug continuously during a period of 12 to 18 hours for 3 to 7 days.* The drug may be delivered

to an infant oxygen hood or tent, by facemask, or through pressure- or volume-cycled ventilators, provided ventilatory pressure is monitored and the device is checked for precipitation, which may cause ventilator dysfunction.^{197,452}

Intermittent high-dose inhaled therapy, with drug administered at 60 mg/mL for 2 hours three times daily for 5 days, also appears to be effective and may be better tolerated in some older patients.¹⁶⁹ Longer courses of aerosolized therapy for up to 14 days have been used in severely immunocompromised patients with prolonged viral shedding and severe disease.³⁷⁰

Oral doses of up to 600 mg twice daily for 24 to 48 weeks, usually combined with interferon alfa, are used to treat hepatitis C in adults.^{55,58,137,147,283,404,481} High doses of oral ribavirin also appear to be effective in treating influenza in normal hosts and RSV infection in immunocompromised hosts.^{372,462,520} Even higher doses of oral ribavirin (2-g loading dose, followed by 2 g/day divided every 8 hours for 10 days) have been used for the treatment of Lassa fever and other hemorrhagic fever syndromes in adults.^{172,185,282,291,311,333,403} Oral doses of ribavirin at 20 mg/kg per day for up to 14 days have been administered to transplant recipients with RSV infection.⁸³

The intravenous dose of ribavirin used to treat Lassa fever is a 2-g loading dose (25–33 mg/kg estimated pediatric dose), followed by 1-g doses (15–16 mg/kg estimated pediatric dose) every 6 hours for 4 days and then 500-mg doses (8 mg/kg estimated pediatric dose) every 8 hours for 3 days to complete a 7- to 10-day course of treatment.^{311,403} This intravenous dosage regimen also has been used to treat measles pneumonia, severe influenza with complications, pneumonia caused by RSV and parainfluenza virus in immunocompromised patients, and disseminated adenovirus disease.^{191,230,382,477} Continuous intravenous infusions of ribavirin have been used in patients with severe disease caused by influenza and parainfluenza viruses.²⁵⁷ Doses used to treat subacute sclerosing panencephalitis in children have been considerably higher and administered for longer periods.^{287,432} In one report, pediatric patients received interferon alfa combined with 10 mg/kg of ribavirin administered intravenously every 8 hours daily for 7 days. Escalating doses of 20 mg/kg and then 30 mg/kg given every 8 hours daily for 7 days at 7-day intervals then were administered.²⁸⁷ The highest dose tolerated was given for 7 days, repeated in 7-day intervals, and administered for a period of 6 months.

Adverse effects. Adverse effects of aerosolized ribavirin are unusual but include local irritation causing facial rash and conjunctivitis. Abnormalities in pulmonary function, including worsening of respiratory distress and bronchospasm, also have been reported.^{212,236,530} In addition, one case of water intoxication associated with aerosolized ribavirin administration has been reported.⁵⁷⁷ Older children, adolescents, and adults may be noncompliant with treatment or may even have anxiety attacks or experience other forms of psychological stress as they are being confined for continuous treatment for a 12- to 18-hour period. In these cases, intermittent, high-dose regimens may be better tolerated and might enhance compliance of the patient.¹⁶⁹ Precipitation of the drug in ventilator tubing systems and on filtering devices may cause ventilator dysfunction and respiratory distress or failure in mechanically ventilated patients, especially those receiving high-dose intermittent administration, but such events may be minimized by frequent monitoring of ventilator pressure, frequent cleaning of the tubing, and frequent changing of the filters.^{197,410,422,452} Adverse hematologic effects, such as anemia, have not been documented consistently in patients who received aerosolized ribavirin. The environmental exposure to aerosolized ribavirin by health care workers providing direct care to a virus-infected patient may, in some instances, cause headache, conjunctivitis, contact lens damage, watery eyes, and bronchospasm in those with underlying reactive airway disease.^{68,212,488,524}

These potential adverse effects are probably more likely to be seen in instances in which ribavirin is administered by hood, tent, or facemask than when it is administered to mechanically ventilated patients.⁶⁹ Environmental exposure of health care workers and family members may be reduced by providing routine patient care during periods when the aerosol generator has been turned off, by turning off the aerosol generator during periods of more urgent care, and by using protective equipment such as masks and goggles. Dose-related, reversible, usually

Pleconaril

FIG. 239.5 Structure of pleconaril.

mild anemia occurs frequently during and after long-term oral therapy and intravenous administration of ribavirin.^{283,314,405} Rarely, severe anemia may occur and necessitate dose reduction or cessation of therapy.⁴⁰⁶ Reversible increases in serum bilirubin, serum iron, and uric acid concentrations also have been documented during oral therapy. On rare occasion, intravenous administration of ribavirin has produced chills and rigors.^{184,212}

Ribavirin has shown teratogenic, mutagenic, and embryotoxic effects in preclinical animal models.²⁷² Therefore investigators recommend that exposure of pregnant women to ribavirin, either therapeutically or through environmental exposure, be minimized or prevented whenever possible or practical.

Pleconaril and Poczavir

Spectrum of Activity

Pleconaril and pocavir are investigational viral capsid inhibitors with activity again various human wild-type and vaccine strain of polio and nonpolio enteroviruses and human rhinoviruses.

Pleconaril (3-[3,5-dimethyl-4-[[3-(3-methyl-5-isoxazolyl)propyl]oxy]phenyl]-5-(trifluoromethyl)-1,2,4-oxadiazole) is an antiviral agent and capsid inhibitor, with significant and specific activity against picornaviruses, both enteroviruses and rhinoviruses (Fig. 239.5). It was developed in the 1990s as a capsid-binding antiviral agent. In vitro, pleconaril inhibits the replication of most serotypes of enteroviruses at concentrations between 0.01 and 0.1 $\mu\text{g/mL}$. Echovirus 11, a commonly isolated enterovirus in the United States, appears to be the most sensitive enterovirus tested to date (inhibited at a mean concentration of 0.006 $\mu\text{g/mL}$), although resistant strains have been reported. Most rhinovirus serotypes are inhibited at slightly higher concentrations of 0.21 to 0.78 mg/mL but still within ranges safely achievable in patients.

Poczavir [1,3-dichloro-2-(oxy)benzene] (V-073 or SCH-48973) is capsid inhibitor, investigational candidate, developed in the 1990s; it currently is being evaluated in clinical trials for treatment of wild-type and vaccine strain poliovirus infections and has variable antiviral activity against nonpolio enteroviruses.^{119,407,579} In vitro, pocavir inhibits human enteroviruses at an IC_{50} of 0.02 to 0.11 $\mu\text{g/L}$, with 80% of isolates inhibited at an IC_{50} of 0.9 $\mu\text{g/mL}$, or from 0.001 to 0.15 $\mu\text{mol/L}$, with 90% of enterovirus isolates inhibited at half maximal effective concentration (EC_{50}) values of less than 0.56 $\mu\text{mol/L}$.⁸²

Mechanism of Action and Resistance

Pleconaril binds efficiently to a specific hydrophobic pocket within the viral capsid of picornaviruses and exhibits an antiviral effect by interfering with uncoating, attachment, and cell-to-cell transmission of infectious viral particles.⁴⁹⁵ The drug induces a more rigid structure within the viral capsid, which then interferes with viral uncoating and release of viral RNA.^{193,408,465,466,489,495} Pleconaril also appears to change the conformation of the canyon floor of the virus capsid when it integrates with the underlying pocket, thereby interfering with attachment of the virus to host cell receptors.^{465,466} Resistance of picornaviruses to pleconaril both has been reported in vitro and has developed in vivo during treatment of enterovirus infections, especially in immune compromised patients.⁴⁷

Poczavir resistance in vitro involves a single amino acid change in one of either of two virus capsid proteins: VP1 or VP3 of enteroviruses. The isoleucine residue at position 194 in capsid protein VP1 is replaced with phenylalanine or methionine, or the alanine at position 24 in VP3 is replaced with valine in resistant strains.¹¹⁹ Resistance occurs in vitro and may emerge in vivo during antiviral treatment.

Pharmacokinetics

The pharmacokinetics of pleconaril vary with the age of the group tested. After oral administration of single doses of 200 to 400 mg to adults, peak plasma concentrations of 1.1 to 2.4 $\mu\text{g/mL}$ are achieved in 1.5 to 5 hours, with an average elimination half-life of 25 hours.² Repeated dosing for a 7-day period increases plasma concentrations to 1.33 to 3.4 $\mu\text{g/mL}$. When pleconaril is taken with food, especially a meal high in fat, absorption is enhanced significantly.^{1,328} Single oral doses of 5 mg/kg in children provide plasma concentrations of approximately 1.3 $\mu\text{g/mL}$, with a more rapid elimination half-life of approximately 6 hours.³²⁷ Neonates also absorb pleconaril well, but they do not exhibit dose-proportionate pharmacokinetics as adults do.³²⁸ The drug also has a large volume of distribution and concentrates in tissues such as the liver, brain, and nasal epithelium, where viral replication and virus-induced disease are likely to occur.³²⁸ Pleconaril appears to be excreted in feces and urine.

Poczavir is well absorbed orally, but there are limited pharmacokinetic data available at this time.¹¹⁹ Mean concentration of drug levels after oral administration have been measured in clinical trials well above the needed antiviral inhibitory concentrations.¹¹⁹

Clinical Indications, Dosage, and Adverse Effects

Clinical indications. Pleconaril, after clinical trial data were reviewed, was disapproved for licensure by the FDA in 2002 because of its modest effectiveness and possible side effects. Pleconaril currently is not licensed for therapeutic use, and it is not available at this time for compassionate use.^{421,610} However, clinical trials continue to evaluate pleconaril for treatment of serious enteroviral disease as well as rhinovirus infection in neonates and children (<https://clinicaltrials.gov>). Pleconaril has shown efficacy in clinical trials against picornavirus infections in adults, children, and neonates.^{3,4} In pretreated adults experimentally infected with coxsackie A21 virus, pleconaril significantly reduced viral titers as well as the clinical parameters of fever, nasal mucus production, and systemic symptoms compared with placebo.^{248,495,510} In another trial, pleconaril resolved the symptoms of illness 2 days earlier than placebo, and patients who received pleconaril did not require as much concomitant medication for symptomatic relief as did those who received placebo.⁴⁹⁵ In two placebo-controlled trials in adults with aseptic meningitis caused by enterovirus, pleconaril treatment reduced the duration of headache and other symptoms of meningitis by 2 to 3 days and allowed treated patients to return to work and routine daily activities 2 days earlier than patients who received placebo.^{495,510} In a placebo-controlled trial in pediatric patients with aseptic meningitis caused by enterovirus, pleconaril significantly improved illness scores and reduced the duration of headache in older children, but clinical efficacy was difficult to assess in infants and younger children.⁴ Viral shedding from the throat also was reduced in the treatment group.⁵⁰⁵

In addition to treatment of the "common cold" and "viral meningitis," another potential use of pleconaril is for the treatment of serious, persistent, or life-threatening illness caused by enteroviruses. More than 90 patients with unusual or life-threatening infections with enterovirus have received pleconaril on a compassionate-use basis.^{193,610} These patients included immunocompromised patients with chronic meningitis, neonates with disseminated disease, patients with myocarditis,^{495,610} and individuals with poliomyelitis associated with vaccine or wild-type poliovirus.⁴⁹⁰ In all groups, most of the patients showed clinical and virologic responses. In a randomized clinical trial in neonates with virologically proven enterovirus sepsis, pleconaril showed shorter times to viral culture and polymerase chain reaction (PCR) test negativity and greater survival among pleconaril recipients compared with placebo recipients.⁴²¹

Poczavir has been developed as a poliovirus antiviral drug to control poliomyelitis outbreaks in the posteradication era. Efforts spearheaded by the Poliovirus Antivirals Initiative, began in 2007, continue to support clinical development of this and other antivirals active against poliovirus.⁴⁰⁷ Prolonged excretion of vaccine-derived polioviruses by immune-deficient persons, especially those persons with primary B-cell immunodeficiency syndromes who inadvertently receive live, attenuated oral poliovirus vaccine and may continue to excrete vaccine-derived virulent virus into the environment, are a potential risk to polio eradication.¹¹⁹ Immunized adults challenged with monovalent poliovirus type 1 vaccine and subsequently treated with pocavir had reduced time

to virus negativity in the stool compared with placebo recipients.¹¹⁹ This indication, to reduce vaccine strain virus shedding in stool, is the primary proposed role for pocapavir. In addition pocapavir may be used to treat inadvertent exposure to vaccine poliovirus during manufacturing or research facilities, as well as outbreak control.⁵⁷⁹

Dosage. Pleconaril is manufactured as a hard gelatin capsule and an oral solution. A nasal spray formulation has also been developed and tested in clinical trials against rhinovirus infection. The capsule contains 200 mg of drug, and doses used in adults and older children have been 200 to 400 mg every 8 hours for 7 days (21 doses). An oral solution also has been prepared for pediatric and neonatal use. It contains 40 mg/mL of pleconaril, medium-chain triglycerides, two surfactants (Tween 80 and Arlacel), 1.5% saccharin, and cherry-peppermint flavoring. Doses of 5 mg/kg, 7.5 mg/kg, and 8 mg/kg of the oral solution administered every 8 to 12 hours for 7 days (14–21 doses) have been used in clinical trials of young children, infants, and neonates.^{495,421}

Adult dosage of pocapavir 1600 mg per day is being evaluated in current clinical trials. No pediatric or neonatal dosing regimens are available at this time.¹¹⁹

Adverse effects. Oral pleconaril is generally well tolerated by all age groups. Adverse effects associated with pleconaril treatment include nausea, diarrhea, stomach upset or discomfort, and headache. Serious toxicities have not been documented to date, and preclinical studies did not show teratogenicity or fetal toxicity. Prolongation of menstrual cycle bleeding in young women taking pleconaril for 6 weeks for upper respiratory virus infections was observed in one clinical trial. Pocapavir is generally well tolerated, with reports of headaches in adults, and possibly mild liver enzyme elevations noted in clinical trials.¹¹⁹

ANTIVIRAL AGENTS ACTIVE AGAINST DNA VIRUSES

Table 239.2 provides a list of antiviral agents active against DNA viruses, including their clinical indications and usual dosages.

Acyclovir

Spectrum of Activity

Acyclovir, 9-[(2-hydroxyethoxy)methyl]-9H-guanine (also known as acycloguanosine), is an analogue of the nucleoside deoxyguanosine that has selective activity against the herpes family of viruses (Fig. 239.6).^{130,165} It has the most potent antiviral activity against HSV type 1 and inhibits the virus at concentrations of 0.02 to 0.9 µg/mL.^{592,608} Inhibitory concentrations of HSV type 2 and VZV are also high, at 0.3 to 2.2 µg/mL and 0.8 to 4.0 µg/mL, respectively.^{54,550,592,608} In addition, EBV replication is inhibited by acyclovir at a mean concentration of 1.6 µg/mL, but the drug has no effect on cells latently infected with EBV.^{114,266,373,566} CMV also is inhibited by very high concentrations of acyclovir (2–57 µg/mL).⁵⁴ Acyclovir has in vitro activity against simian herpesvirus B and hepatitis B virus (HBV).^{49,285,592}

Mechanism of Action and Resistance

Acyclovir is phosphorylated to acyclovir monophosphate by viral TK. Cellular enzymes then convert the monophosphate form to acyclovir triphosphate, the active form of the drug.⁶⁰⁸ Acyclovir triphosphate is

Acyclovir

FIG. 239.6 Structure of acyclovir.

TABLE 239.2 Clinical Indications and Usual Treatment Dosages for Licensed Antiviral Agents Active Against DNA Viruses

Agent	Indication	Dosage
Acyclovir	HSV, mucocutaneous	5% ointment 6 × daily 15 mg/kg/dose PO 5 × daily (max 200 mg/dose) 5–10 mg/kg/dose IV q8h
	HSV, encephalitis	10–15 mg/kg/dose IV q8h
	HSV, neonatal	20 mg/kg/dose IV q8h
	VZV, chickenpox and zoster	20 mg/kg/dose (max 800 mg) PO q6h 10–20 mg/kg/dose (500 mg/m ² /dose) IV q8h
Valacyclovir	HSV VZV, zoster	500–1000 mg/dose PO bid 1000 mg/dose PO bid
Penciclovir	HSV, mucocutaneous	1% cream q2h
Famciclovir	HSV, mucocutaneous VZV, zoster	125–500 mg PO bid 500 mg PO tid
Ganciclovir	CMV	5–6 mg/kg/dose IV q12h—induction 5 mg/kg/dose qd 5 days/wk or 1000 mg PO tid or 500 mg PO 6 × daily—maintenance
Valganciclovir	CMV	900 mg PO bid—induction 900 mg PO qd—maintenance 15–18 mg/kg/dose every 12 h or bid
Foscarnet	CMV	60 mg/kg/dose IV q8h—induction 90–120 mg/kg/dose daily—maintenance
Cidofovir	CMV	5 mg/kg/dose IV weekly Or 1 mg/kg/dose IV 3 ×/wk—induction 5 mg/kg q2wk—maintenance

CMV, Cytomegalovirus; HSV, herpes simplex virus; VZV, varicella-zoster virus.

present in HSV-infected cells at 40 to 100 times the concentration found in uninfected cells, and it competitively inhibits viral DNA polymerase in infected cells. Acyclovir triphosphate also is incorporated into viral DNA and, because it lacks the 3'-hydroxyl group, acts as a chain terminator during viral DNA synthesis. The DNA polymerase enzymes of the various herpesviruses differ in their degree of inhibition by acyclovir triphosphate, and for EBV and CMV, which do not contain viral TK, this inhibition accounts for most of the antiviral effect of the drug.^{144,200} Host cellular growth also can be inhibited by acyclovir, but only at levels thousands of times higher than those that inhibit viral replication. This relatively selective mechanism of antiviral action provides a uniquely high therapeutic index.

Three basic mechanisms of resistance have been identified for herpesviruses to become resistant to acyclovir: deficient TK activity caused by absent or low production of viral TK, altered TK activity caused by abnormal substrate specificity so that the enzyme is present and able to phosphorylate but just does not phosphorylate acyclovir, and altered DNA polymerase.⁹⁵ Most clinical isolates of HSV that are resistant to acyclovir have deficient TK activity, and most resistant VZV isolates have altered TK activity or altered DNA polymerase.^{460,573} The prevalence of acyclovir-resistant HSV isolates in normal hosts is less than 1%, but it can be as high as 10% to 20% in immunocompromised hosts receiving acyclovir therapy for 2 weeks or longer.^{107,129,171,205,269} Emergence of acyclovir-resistant HSV type 1 through both viral thymidine kinase and DNA polymerase mutations in hematopoietic stem cell transplantation patients has been observed in 28% of patients shedding HSV type 1 and also has been associated with relapsed malignancies and higher mortality rates.³¹⁸ Resistant strains of VZV, on the other hand, are unusual.¹¹⁵ Resistant HSV and VZV isolates retain virulence and can cause disease, especially extensive mucocutaneous lesions in immunocompromised hosts, but invasive diseases such as keratitis, uveitis, meningoencephalitis, and pneumonia also have occurred with resistant strains of HSV.^{107,171,205,269,308,580} Immunocompromised hosts may shed resistant strains of HSV for prolonged periods and may experience recurrent disease with either sensitive or resistant strains. Such mutants are also cross-resistant to other antiviral agents that require viral TK for phosphorylation and activation (e.g., penciclovir and ganciclovir), but they are inhibited by antiviral agents that have different mechanisms of action (e.g., foscarnet, cidofovir, and trifluridine).

Pharmacokinetics

Acyclovir is available for topical, oral, and intravenous administration. Systemic absorption of acyclovir after topical application to intact skin is minimal (<0.01 µg/mL), and in one study in which acyclovir ointment was applied to zoster lesions in immunocompromised patients, plasma concentrations of less than 0.1 to 0.78 µg/mL were observed, thus suggesting some degree of percutaneous absorption.^{124,592} The bioavailability of oral acyclovir is low (15–21%), with peak plasma concentrations of 0.4 to 0.8 µg/mL observed after the intake of one 200-mg capsule and concentrations of up to 1.6 µg/mL observed after an 800-mg dose.⁵⁷ When an equivalent dose in liquid suspension is administered to children, slightly lower peak plasma levels of 1.0 µg/mL are observed.⁵⁶⁵ Intravenous infusion of 5 mg/kg for 1 hour provides peak plasma levels of 9.8 µg/mL, whereas plasma levels of 20.7 µg/mL are produced after a 10-mg/kg infusion.⁶³ Most of the administered dose of acyclovir is excreted unchanged in urine.⁵⁹² The elimination half-life of acyclovir is 2.5 to 3 hours in adult patients with normal renal function, slightly longer (3.8 hours) in neonates, and up to 20 hours in anuric patients.^{57,196,273} Therefore dose adjustment, according to creatinine clearance, is needed in patients with renal insufficiency or renal failure.³⁶² Probenecid administration decreases renal clearance and prolongs the half-life of acyclovir. Acyclovir is distributed widely into a variety of body fluids, including saliva (13% of plasma levels), vaginal secretions (15–170% of plasma levels), zoster vesicular fluid (90–100% of plasma levels), aqueous humor (37% of plasma levels), breast milk (>300% of plasma levels), amniotic fluid and placenta (>200% of plasma levels), and CSF (50% of plasma levels).^{196,293,294,340,363,416} More than half the drug is removed by hemodialysis, but very little is removed after peritoneal dialysis.^{351,362}

Clinical Indications, Dosage, and Adverse Effects

Clinical indications. Topical acyclovir may decrease healing time and viral shedding slightly in mucocutaneous lesions of patients experiencing primary infection with HSV.¹²⁴ Little if any clinical benefit has been documented in patients with recurrent herpes simplex lesions; however, some patients report a soothing sensation after application of ointment to the lesions. Topical therapy also may produce a mild clinical benefit in immunocompromised patients with zoster lesions.⁵⁹² Oral acyclovir significantly reduces viral shedding, clinical symptoms, and time until lesion healing in normal and immunocompromised patients with a variety of mucocutaneous lesions (e.g., orolabial, pharyngeal, genital, rectal, gingivostomatitis, whitlow, skin) associated with primary HSV infection.^{13,491,608} It also has been used to treat eye disease, including dendritic corneal ulcers.^{120,264}

Oral acyclovir provides benefit to normal and immunocompromised children, adolescents, and adults with primary infection with VZV (varicella or chickenpox). Treatment reduces the duration of fever by 24 hours, the mean number of skin lesions, and the time to total crusting of lesions by 2 days. Postexposure prophylaxis with oral acyclovir also may reduce the risk for acquiring varicella by close and household contacts of patients with varicella. Administration of oral acyclovir during pregnancy is likely to clinically benefit a mother with varicella, but whether it reduces the risk for congenital or neonatal disease is not clear at this time. Recurrent HSV disease also is improved with oral acyclovir therapy. When it is administered during the prodrome or at the very first sign of lesions, treatment reduces viral shedding and time to lesion healing by 1.5 to 2 days.^{482,593} Long-term, continuous suppressive therapy with oral acyclovir may be of benefit in some patients with frequent episodes of recurrent mucocutaneous disease, but asymptomatic shedding and person-to-person transmission still may occur.^{214,492} Patients with recurrent skin disease, whitlow, or erythema multiforme may benefit from long-term suppressive therapy with oral acyclovir. Oral acyclovir suppression also reduces recurrences of genital herpes simplex during the last trimester of pregnancy and decreases the need for cesarean delivery.^{74,513,516-518} Short-term prophylaxis administered during a period of risk for recurrence (e.g., sunlight exposure) may reduce the clinical recurrence of mucocutaneous disease. Oral acyclovir reduces virus shedding, time to skin lesion healing, and the duration of zoster-associated pain.^{43,113} Treatment combined with steroids also appears to decrease the frequency and severity of postherpetic neuralgia in older adult patients, but specific trials conducted in children have not been performed because children seldom experience postherpetic neuralgia. Oral acyclovir also may reduce recurrence of HSV and VZV infections in bone marrow and solid-organ transplant recipients. Its effect on CMV and EBV disease in these patients, however, is minimal, if any.⁵⁶⁶ Continuous suppressive therapy with oral acyclovir reduces cutaneous recurrences after neonatal infection when it is administered after a 14- to 21-day course of intravenous therapy has been completed.³³⁹ Whether long-term oral suppressive therapy in neonates also prevents CNS recurrence is unclear at this time. Bell palsy associated with HSV infection may be treated with a combination of acyclovir and prednisone.⁶ EBV-associated diseases have been treated with acyclovir, with variable clinical benefit.^{513,526} Oral hairy leukoplakia, however, appears to respond to oral acyclovir treatment.^{484,582} Treatment of patients with infectious mononucleosis reduces viral shedding but does not alter the disease course.⁵⁴¹ No clinical benefit has been documented when acyclovir was used to treat chronic hepatitis B.⁴⁹

Intravenous acyclovir is used to treat all severe or life-threatening diseases caused by HSV and VZV, including encephalitis, hepatitis, neonatal disease, acute retinal necrosis syndrome, mucocutaneous disease, and zoster, with or without visceral dissemination, in both normal and immunocompromised patients.^{63,231,336,342,353,457,591,624} Pediatric patients suffering from severe herpetic gingivostomatitis may benefit as well.¹³ Early clinical trials also showed efficacy in the treatment of primary genital HSV infection.¹²³ In addition, normal patients with complications of varicella, including pneumonitis, encephalitis, and hepatitis, should receive intravenous acyclovir.²³¹ Other diseases associated with VZV in which acyclovir treatment is beneficial include zoster ophthalmicus with complications such as keratitis, anterior uveitis, and contralateral hemiplegia, as well as acute retinal necrosis syndrome.^{457,539} Intravenous

acyclovir is also highly effective in reducing the incidence of disease associated with HSV and VZV in marrow and solid-organ transplant recipients. Moreover, it may help reduce serious CMV disease in selected marrow and solid-organ transplant recipients, although it clearly is not as effective as ganciclovir or other antiviral agents with specific activity against CMV.^{28,29,60,417,587} Treatment of human herpes infection with simian virus B requires high doses of intravenous acyclovir administered for a prolonged period, followed by suppressive therapy.²⁸¹ Despite in vitro activity, clinical benefit has not been documented in patients with hepatitis B.⁴⁹

As of November 2012, a shortage of intravenous acyclovir related to manufacturing delays was announced. If the shortage is still in effect, or if another shortage occurs, ganciclovir, or foscarnet secondarily, is recommended for most patients who would ordinarily have received intravenous acyclovir (<https://redbook.solutions.aap.org/ss/acyclovir-shortage.aspx>). Cidofovir also has activity against HSV and VZV and may also be considered in selected patients.

Dosage. Topical acyclovir as a 5% ointment can be applied to local lesions every 3 to 4 hours five to six times daily for 7 days.¹²⁴ If the disease is unresponsive or severe, systemic therapy with oral or intravenous acyclovir should be initiated.

Oral acyclovir is formulated as 200-mg capsules, 800-mg tablets, and a 200-mg/5 mL banana-flavored suspension. The usual dose used to treat mucocutaneous lesions caused by primary infection with HSV in adults and adolescents is 200 mg administered five times daily for 10 days. The usual pediatric oral dose is 15 mg/kg per dose (maximum, 200 mg per dose) administered five times daily for 10 days. Recurrent HSV disease in adults and adolescents may be treated with a variety of different regimens: 800 mg three times daily for 2 days, 400 mg three times daily for 5 days, or 200 mg five times daily for 5 days.^{323,324,593} Suppressive doses of 400 mg administered twice daily, often for many years, seem to be safe and effective.²¹⁴ This dose, administered to pregnant women with recent primary or recurrent genital herpes, also appears to decrease recurrences at or near delivery and to diminish the need for cesarean delivery.^{74,340,559} After intravenous therapy has been completed, neonatal suppressive therapy is recommended at a dose of 300 mg/m² per dose administered three times daily for 6 months.³³⁹ Because neonatal prophylaxis decreases but does not eliminate the risk for CNS recurrence and because the emergence of resistant strains has been documented, all early cutaneous lesions that recur despite compliance with oral prophylaxis, as well as other signs and symptoms suggestive of recurrent visceral or CNS disease, should be evaluated carefully in young infants, and the need for systemic therapy should be considered.³³⁹ Oral acyclovir must be administered in higher doses to treat varicella and other VZV-associated diseases.⁶⁰⁸ Adults and adolescents require 800-mg doses administered five times daily for 7 to 10 days or until lesions have crusted over.^{33,595} The pediatric dose of acyclovir to treat varicella or chickenpox is 20 mg/kg (up to 800 mg maximum) per dose (80 mg/kg/day) administered four times daily for 5 days or until lesions have crusted.^{9,160}

The usual dose for intravenous administration of acyclovir to treat serious disease associated with HSV beyond the neonatal period is 5 to 10 mg/kg per dose administered as a 1-hour infusion every 8 hours.^{473,592,608} Treatment for a duration of 7 days is usually sufficient for mucocutaneous disease, but it should be continued until all lesions are healed and followed by long-term suppression if the patient remains immunocompromised. Herpes encephalitis should be treated for at least 14 days or longer, depending on clinical response and clearance of HSV DNA from the CSF.^{337,336,355,607}

The recommended dose to treat all forms of neonatal HSV disease (skin, eye, and mouth disease; disseminated with visceral involvement; or encephalitis) is a high-dose regimen of 20 mg/kg per dose administered every 8 hours (60 mg/kg per day).¹⁰ This high dose of intravenous acyclovir, although not currently formally approved by the FDA, has been shown to be safe and effective in neonates.^{174,336} Duration of intravenous treatment is at least 14 days for skin, eye, and mouth disease and at least 21 days or until HSV DNA has cleared from the CSF, whichever is longer, for encephalitis and disseminated disease.^{337,336} Persistence of HSV DNA in the CSF of neonates treated for 21 days with high-dose acyclovir is seen, and these patients usually have a more

severe clinical course and poor neurodevelopmental outcome.⁴⁵¹ Intravenous acyclovir treatment for neonatal HSV disease should be followed by suppression treatment with oral acyclovir at 300 mg/m² per dose every 8 hours until at least 6 months of age to reduce risk for recurrences and to improve neurodevelopmental outcome.¹⁰ Clinical studies have documented that these higher doses are safe in neonates but may cause renal insufficiency in older children and adults. Treatment of VZV-associated disease requires higher doses of acyclovir: 500 mg/m² per dose (10–20 mg/kg per dose) administered every 8 hours (total, 1500 mg/m² per day) for at least 5 to 7 days or until all lesions have been crusted over for 24 to 48 hours.^{592,608} In all clinical indications, the dosage of intravenously administered acyclovir should be adjusted according to creatinine clearance in patients with renal insufficiency and renal failure.

Adverse effects. Adverse effects of acyclovir are unusual.³³⁰ Topical application of the ointment may produce pain or local irritation, usually caused by the polyethylene glycol base.^{124,592} Hand washing must be performed after each local application to lesions to avoid autoinoculation or person-to-person transmission. Oral acyclovir may cause nausea and diarrhea, rash, or headache.⁵⁹² Long-term oral administration of acyclovir appears to be safe in adults but may be associated with neutropenia in 46% of infants who receive suppression after treatment of neonatal HSV infection.^{339,419} Intravenously administered acyclovir is generally well tolerated. However, extravasation of the drug (pH 9–11) can cause inflammation, ulceration, and necrosis of surrounding tissue.^{330,438,529,569} Phlebitis also can develop. Neurotoxicity occurs rarely, usually in patients with renal insufficiency who have high serum concentrations.^{42,181,232,590} Neurotoxicity associated with acyclovir is characterized by lethargy, confusion, tremor, and rarely seizures and coma. Renal tubular damage, crystalline nephropathy, or interstitial nephritis may occur in approximately 5% of patients.^{476,506} These renal complications are more likely to develop in patients who are not adequately hydrated or in whom the drug has been infused at a rate faster than the recommended infusion time of 1 hour. Keeping urine-specific gravity below 1.010 is a reasonable guideline to ensure adequate hydration. No excess frequency of adverse events has been reported to date in pregnant women who receive acyclovir or in their fetuses or newborns.^{74,91,340,513,518,624} Therefore, on the basis of available information, acyclovir seems to be safe when it is administered during pregnancy, especially during the last trimester, and does not appear to have any significant adverse effects.

Valacyclovir

Spectrum of Activity

Valacyclovir (L-valine, 2-[(2-amino-1,6-dihydro-6-oxo-9H-purin-9-yl)methoxy]ethyl ester monohydrochloride, also known as valacyclovir hydrochloride) is the hydrochloride salt of the L-valine ester of acyclovir.⁴⁴ It has essentially the same selective spectrum of antiviral activity against the herpesviruses as acyclovir does.⁵¹

Mechanism of Action and Resistance

Valacyclovir is converted rapidly to acyclovir and therefore has the same mechanisms of action and resistance as acyclovir.⁵¹ Viral isolates that are resistant to acyclovir will be resistant to valacyclovir.

Pharmacokinetics

The pharmacokinetics of valacyclovir has not been studied in the pediatric population, but information gained from adults can be applied, in many ways, to pediatric patients. After oral administration, valacyclovir is absorbed rapidly from the gastrointestinal tract. It is metabolized by first pass through the intestinal tract and also by the liver into acyclovir and L-valine.⁵¹ It has the advantage over acyclovir of having 54% bioavailability (vs. 20% for acyclovir), which is not altered by food.⁵⁴⁵ A single dose of 1 g of valacyclovir administered to an adult produces plasma levels of 0.4 to 0.8 µg/mL. The half-life is 2.5 to 3 hours, similar to that of acyclovir, and is prolonged in patients with renal insufficiency or renal failure.^{597,601} The drug is removed by hemodialysis. The rate but not the extent of conversion of valacyclovir to acyclovir is prolonged in patients with liver disease.

Clinical Indications, Dosage, and Adverse Effects

Clinical indications. Valacyclovir has been reported to be effective in treatment of primary and recurrent mucocutaneous disease caused by HSV-1, HSV-2, and VZV.^{51,51,59,369,483,465} Randomized clinical trials conducted in adult patients showed valacyclovir to be superior to placebo and comparable to acyclovir in reducing the number and duration of lesions, pain, and time to healing in patients with primary and recurrent genital herpes and zoster.^{59,483,552,617} It is also comparable to acyclovir for suppression of genital herpes recurrences. Furthermore, in a study of 27 CMV-seropositive heart transplant recipients, valacyclovir appeared to be equal or superior to oral acyclovir in preventing both laboratory and clinical parameters of CMV reactivation.¹⁶² Because valacyclovir is converted to acyclovir, it is likely to be effective for all the clinical indications for which acyclovir has been shown to be effective.

Dosage. Valacyclovir is available only in 500-mg caplets; therefore a pediatric liquid formulation is not available at this time. The usual dose is 1 g twice daily for 10 days for primary genital herpes and 500 mg twice daily for 3 to 5 days for recurrent disease.^{51,59,369,510} A daily dose of 500 mg has been used safely for longer than a year to suppress recurrences of HSV disease.³⁹² The dose to treat VZV-associated disease is higher than that for HSV-associated disease. A dose of 1 g three times a day for at least 7 days is usually necessary to treat zoster, and therapy should be continued until the lesions have dried.⁵² The dose of valacyclovir should be adjusted according to creatinine clearance in patients with renal insufficiency or renal failure.

Adverse effects. The adverse effects of oral valacyclovir are similar to those of oral acyclovir and include gastrointestinal disturbances such as nausea, vomiting, and diarrhea.⁵¹ Headache and behavioral changes also have been observed. Overdosage may produce precipitation of acyclovir in the renal tubules as well as CNS toxicity.

Penciclovir

Spectrum of Activity

Penciclovir (9-[4-hydroxy-3-hydroxymethylbut-1-yl] guanine) is an acyclic guanosine analogue with a selective spectrum of activity against the herpesviruses similar to that of acyclovir⁶⁷ (Fig. 239.7). This compound inhibits HSV-1 at very low concentrations (0.2–0.6 µg/mL) and HSV-2 at slightly higher concentrations (0.3–2.4 µg/mL).^{26,67,216,600} At even higher concentrations (0.9–4.0 µg/mL), it inhibits VZV.^{26,27} The compound has very little activity against CMV, and concentrations greater than 50 µg/mL are required to inhibit CMV. However, penciclovir does have activity against HBV.^{118,349,522}

Mechanism of Action and Resistance

Like acyclovir, penciclovir is preferentially phosphorylated by viral TK in virus-infected cells to penciclovir monophosphate and by cellular enzymes to penciclovir triphosphate, which is the active form of the drug.¹⁶¹ Penciclovir triphosphate competitively inhibits viral DNA polymerase. It is approximately 100 times less potent than acyclovir triphosphate in inhibiting viral DNA polymerase, but an antiviral effect is achieved because it is present in high concentrations for a prolonged period (7–20 hours) in virus-infected cells. However, unlike acyclovir, penciclovir is not a chain terminator during DNA synthesis. Penciclovir triphosphate also inhibits the DNA polymerase of HBV. Emergence of HSV strains resistant to penciclovir has been minimal.³⁶⁶ Similar to HSV isolates resistant to acyclovir, isolates resistant to penciclovir may have viral TK gene mutations that produce mutants with deficient or

altered TK activity, or they may have mutations in DNA polymerase genes.¹⁰¹ Strains of acyclovir-resistant HSV that are TK-deficient mutants also will be resistant to penciclovir, but strains of acyclovir-resistant HSV that are TK altered may be susceptible to penciclovir.^{68,463}

Pharmacokinetics

Penciclovir is poorly absorbed after oral administration.¹⁹² Adults who received a 10-mg/kg intravenous infusion of penciclovir had plasma levels of 12 µg/mL, but no pediatric information is available. Penciclovir 1% cream is not absorbed systemically. The systemic pharmacokinetics of penciclovir is discussed under famciclovir.

Clinical Indications, Dosage, and Adverse Effects

Penciclovir is available in the United States as a 1% cream in a propylene glycol base and is licensed for the treatment of herpes labialis lesions on the lips and face. Maximal clinical benefit occurs when the cream is applied to the lesions early, at the first clinical sign of disease, every 2 hours while awake for 3 to 5 days.^{509,551} Application of penciclovir cream may be associated with local skin reactions, most likely caused by the propylene glycol base. An intravenous form of penciclovir has been tested in Europe, but it is not available in the United States. Penciclovir is not absorbed orally, but it is available as the oral prodrug famciclovir, which is converted rapidly to penciclovir. Dosages and systemic adverse effects of penciclovir are discussed under famciclovir.

Famciclovir

Spectrum of Activity

Famciclovir, 2-[(2-amino-9H-purin-9-yl)]-1,3-propanedial diacetate, is the prodrug of the antiviral agent penciclovir, which has selective activity against HSV-1, HSV-2, VZV, and HBV.

Mechanism of Action and Resistance

Famciclovir undergoes rapid transformation to penciclovir, which is monophosphorylated by viral TK to penciclovir monophosphate; the monophosphate, in turn, is converted by cellular enzymes to penciclovir triphosphate, the active form of the antiviral compound. Penciclovir then competitively inhibits viral DNA polymerase and, thereby, viral replication. The prolonged intracellular half-life observed with penciclovir also is observed with famciclovir. Penciclovir-resistant strains of HSV and VZV occur when mutations produce deficient or altered TK or altered DNA polymerase. Most TK-deficient acyclovir-resistant strains of HSV are also resistant to penciclovir.

Pharmacokinetics

Famciclovir is the diacetyl-6-deoxy analogue of the antiviral compound penciclovir. After oral administration, famciclovir is absorbed rapidly from the gastrointestinal tract with excellent (77%) bioavailability, and then it is metabolized in the liver by deacetylation and oxidation to form penciclovir. Single oral doses of 250 and 500 mg of famciclovir administered to adults produce peak plasma penciclovir levels of 1.6 to 1.9 µg/mL and 2.7 to 4.0 µg/mL, respectively. Administration of famciclovir with food reduces peak plasma concentrations by slowing the absorption time but does not alter the overall bioavailability of the drug. The half-life for penciclovir is 2 to 3 hours, after which it is excreted by filtration and active tubular secretion by the kidneys. Nonrenal clearance by fecal excretion also occurs for as much as one-third of the oral dose. Excretion of penciclovir is decreased in patients with renal insufficiency and renal failure, and in patients with liver disease, peak plasma levels may be reduced.⁶¹ Penciclovir is removed from the body by hemodialysis. After oral administration of famciclovir to rats, penciclovir is concentrated in breast milk; however, no studies have been performed in lactating mothers to confirm such concentration in humans.

Clinical Indications, Dosage, and Adverse Effects

Clinical indications. In adult clinical trials, oral famciclovir was as effective as oral acyclovir and superior to placebo in treatment of recurrent mucocutaneous infections with HSV and VZV in both normal and immunocompromised patients.^{110,393,497,583} When famciclovir was

Penciclovir

FIG. 239.7 Structure of penciclovir.

given early in the course of illness, time to lesion crusting and healing, duration of viral shedding, and length of acute pain all were shortened. In some studies, the duration of postherpetic neuralgia in older adult patients with zoster also was shortened.⁵⁸³ Although to date it has not been studied specifically in clinical trials of patients with primary HSV and VZV infection, famciclovir probably also will provide clinical benefit in these conditions.³⁸¹ In addition, famciclovir is effective as suppressive therapy to reduce HSV recurrences and viral shedding.^{146,415} Famciclovir also has been used to treat chronic HBV infection and for prophylaxis against recurrent HBV infection in liver transplant recipients.^{237,393} No clinical trials in pediatric patients have been conducted.

Dosage. Famciclovir is available in 125-, 250-, and 500-mg tablets. An oral suspension for pediatric use is not available. The usual recommended oral dose of famciclovir to treat primary and recurrent mucocutaneous HSV disease is 125 mg twice daily for 5 days.⁴⁹⁷ Dosages of suppressive therapy are slightly higher, 250 mg twice daily for as long as 1 year. Of note, clinical trials showed that single daily doses of 250 mg were not as effective as the twice-daily regimen in suppressing recurrences. For immunocompromised patients, especially those infected with HIV, even higher doses (500 mg twice daily for 7 days) may be necessary.⁵⁰⁷ Treatment of VZV-associated disease, such as zoster, also requires higher doses (500 mg twice or three times daily for 10 days).⁵⁸³ All dosage regimens should be reduced, according to creatinine clearance, in patients with renal insufficiency or renal failure.

Adverse effects. Adverse effects of treatment with oral famciclovir are unusual and include gastrointestinal disturbances, such as nausea and diarrhea; rash; CNS complaints, such as confusion, hallucinations, and disorientation; neutropenia; and elevated liver transaminases.^{110,134,502}

Ganciclovir

Spectrum of Activity

Ganciclovir, 9-(1,3-dihydroxy-2-propoxymethyl)guanine (also known as DHPG), is an analogue of deoxyguanosine, similar to acyclovir, yet different in that it has an additional hydroxymethyl group on the acyclic side chain^{179,183,470,531} (Fig. 239.8). This antiviral compound has selective activity against the herpesviruses, with uniquely potent antiviral activity

FIG. 239.8 Structure of ganciclovir.

against CMV. Ganciclovir inhibits HSV-1 and HSV-2 at 0.05 to 0.6 $\mu\text{g}/\text{mL}$, VZV at 0.4 to 10 $\mu\text{g}/\text{mL}$, CMV at 0.02 to 3.4 $\mu\text{g}/\text{mL}$, and EBV at 1.5 $\mu\text{g}/\text{mL}$. Human herpesvirus types 6 (HHV-6), 7 (HHV-7), and 8 (HHV-8) also may be inhibited by ganciclovir.³²⁹ It has in vitro activity against adenoviruses and HBV as well.^{179,211,430,537} High concentrations (30 to >700 $\mu\text{g}/\text{mL}$) of ganciclovir will inhibit the growth of most uninfected mammalian cells; bone marrow–derived cells, however, appear to be uniquely sensitive and can be inhibited at much lower concentrations (<0.7 $\mu\text{g}/\text{mL}$).

Mechanism of Action and Resistance

Ganciclovir is monophosphorylated in infected cells by virus-induced enzymes: TK in HSV-infected cells and protein kinases that are encoded by the UL97 phosphotransferase gene in CMV-infected cells.^{54,179,376,531} Cellular enzymes complete the phosphorylation to ganciclovir triphosphate, the active form of the compound, which is concentrated in infected cells. Ganciclovir triphosphate competitively inhibits the incorporation of deoxyguanosine triphosphate into viral DNA, where it slows and stops viral DNA chain elongation and produces short, noninfectious viral DNA fragments.²⁴⁰ Ganciclovir also preferentially inhibits viral DNA polymerase.³⁸⁴ Ganciclovir resistance has been detected in 8% to 38% of immunocompromised adult and pediatric patients who have received prolonged administration of ganciclovir, and such resistance is an important clinical problem.^{104,155,210,511,543,578}

Patients may be infected with single or multiple strains of CMV, with both drug-sensitive and drug-resistant strains mixed in the population or in different body compartments.¹⁷³ Resistant strains may be induced or infect a patient primarily, emerge quickly after only weeks of therapy, or evolve more slowly and emerge sequentially after several months of antiviral prophylaxis or therapy.^{105,173,304,493,608,618} These resistant mutants also retain virulence and are capable of producing serious and progressive disease.^{62,173,304,500,538} Ganciclovir resistance in CMV strains occurs by at least two mechanisms: (1) point mutations or deletions in the UL97 gene that reduce intracellular phosphorylation of ganciclovir and (2) point mutations in the viral DNA polymerase UL54 (pol) gene that alter the function of the polymerase.^{104,384,535,553} Most strains of CMV that are resistant to ganciclovir have UL97 mutations (most commonly at codons 460, 520, 594, and 595) and reduced phosphorylation, but they remain susceptible to foscarnet and cidofovir.^{103,104,553} The most common specific UL97 mutations associated with ganciclovir resistance include A594V, L595S, M460I/V, C592G, H520Q, and C603W (Fig. 239.9A). Each of these specific mutations increases the EC_{50} of ganciclovir against CMV by 5- to 10-fold, whereas C592G causes only a 3-fold increase in EC_{50} . Other, less known mutations may also be detected and confer functional resistance. However, CMV strains that are resistant to ganciclovir because of a mutation in the UL54 DNA polymerase gene also may be resistant to foscarnet or cidofovir, or to both.^{384,503} Moreover, multiple highly resistant strains of CMV may occur if both UL97 phosphotransferase and UL54 DNA polymerase gene

FIG. 239.9 Mutations associated with resistance to antiviral drugs. (A) The representation of the amino acid sequence of the UL97 kinase is shown with mutations associated with ganciclovir and maribavir resistance shown in red and blue, respectively. Polymorphisms observed in clinical specimens are shown in green. Conserved regions are designated by blue brackets. (B) The DNA polymerase amino acid sequence is depicted with mutations associated with ganciclovir, cidofovir, and foscarnet resistance shown in red, blue, and black, respectively. Conserved motifs are designated with blue brackets. (From James S, Prichard M. The genetic basis of human cytomegalovirus resistance and current trends in antiviral resistance analysis. *Infect Disord Drug Targets* 2011;11[5]:504-513.)

mutations are present.^{105,535} Resistance conferred by UL54 mutations usually emerges after UL97 mutations have occurred.^{210,535} Ganciclovir resistance in HSV occurs in TK-deficient, acyclovir-resistant strains of the virus.

Pharmacokinetics

Intravenous administration of a 5-mg/kg dose of ganciclovir in adults produces peak plasma levels of 8 to 11 µg/mL.^{179,187} Similar pharmacokinetics in 10 pediatric patients aged 9 months to 12 years has been observed.²⁰¹ A study of the pharmacokinetics of ganciclovir in 27 neonates aged 2 to 49 days who were administered intravenous ganciclovir for treatment of congenital CMV disease showed a dose of 6 mg/kg to be the most appropriate dose for that age group, down to 32 weeks of gestation.^{580,631} After intravenous administration, ganciclovir is distributed in CSF at 24% to 70% of plasma levels, and 38% of plasma levels enter brain tissue.^{108,110} Drug levels in aqueous, vitreous, and subretinal fluid in the eye are comparable to serum levels, and even higher levels can be achieved with intravitreal implants.^{20,187,352,396,431} Ganciclovir also accumulates in breast milk in animal models.⁷ The plasma half-life is 2 to 4 hours in adults with normal renal function and longer than 24 hours in patients with renal insufficiency and renal failure.⁵⁴¹ The drug is eliminated by renal excretion, and dose reduction is required for patients with impaired creatinine clearance. Hydration will enhance elimination of the drug, and hemodialysis removes 60% of ganciclovir in plasma.⁵⁴¹ Ganciclovir also can be administered orally.⁵⁴⁷ Its oral bioavailability is rather poor: 5% under fasting conditions and 6% to 9% if it is administered with food.^{15,364} Oral doses of 1000 mg administered to adults every 8 hours produce plasma levels of 0.9 to 1.2 µg/mL.^{15,505} The valine ester prodrug of ganciclovir, valganciclovir, has high oral bioavailability and efficacy equal to that of intravenous ganciclovir for prevention and treatment of mild to moderate CMV disease in transplant recipients and treatment of congenitally infected newborns.^{163,319,394}

Clinical Indications, Dosage, and Adverse Effects

Clinical indications. Ganciclovir is used for the treatment of established CMV disease; for early or preemptive therapy in immunocompromised patients with virologic markers of active infection that are predictive of CMV disease; and for prophylaxis of high-risk patients, such as those who are CMV seropositive or who have received transplants from CMV-seropositive donors.⁸¹ Ganciclovir is licensed for treatment and chronic suppression of sight-threatening CMV retinitis in immunocompromised patients and for prevention of CMV disease in transplant recipients. Clinical trials have demonstrated efficacy in these conditions.* Treatment with ganciclovir also is beneficial in immunocompromised individuals with other forms of invasive CMV disease, including pneumonia, colitis, esophagitis, myocarditis, encephalitis, persistent fever and leukopenia syndrome, and viral sepsis syndrome.[†] Treatment of established CMV pneumonia in bone marrow and stem cell transplant recipients is difficult, and the disease may not respond to ganciclovir treatment, with or without immune modulators or globulins.¹⁶⁷ Most clinical trials have been performed in adults, but children and infants with CMV disease benefit from treatment as well.

Ganciclovir treatment also has been evaluated in newborns congenitally infected with CMV with CNS involvement.^{336,539,631} In addition, ganciclovir is used for preemptive therapy for patients (primarily recipients of solid-organ, marrow, and stem cell transplants) with virologic markers that are predictive of serious CMV disease.^{73,218,266,549} Prophylaxis with ganciclovir to prevent CMV infection and disease in immunocompromised patients, including solid-organ and bone marrow transplant recipients and patients with acquired immunodeficiency syndrome (AIDS), also has been beneficial in most groups studied.^{73,153,159,217,549,615,616} Prophylaxis reduces the risk for the acquisition of serious CMV disease or, in some groups, prolongs the incubation period, but it does not eliminate the risk.^{159,217,553,615} Ganciclovir prophylaxis is also effective in preventing HSV infection in immunocompromised patients.²¹⁷ Ganciclovir appears to decrease HBV DNA levels and to improve hepatic enzymes in patients with posttransplantation infection or reactivation with HBV.²¹¹ In addition,

ganciclovir has been used to treat patients with serious disease associated with adenovirus infection, but clinical trials proving efficacy have not been performed.⁵⁷⁵

Dosage. Ganciclovir is supplied as a solution for intravenous infusion. The intravenous infusions are delivered best in a concentration of 10 mg/mL or less and administered during a 1-hour period. Intravitreal implants are also available and are designed to slowly release relatively large doses of ganciclovir locally into the eye during a period of many months.

Ganciclovir therapy for serious CMV disease outside the newborn period usually is administered in two phases, induction and maintenance. The recommended dose for induction therapy for serious CMV disease in adults and children with normal renal function is 5 mg/kg per dose administered intravenously every 12 hours for 2 to 3 weeks. Successful induction therapy is accompanied by clinical and virologic response. Maintenance therapy at doses of 5 mg/kg per dose administered intravenously every 12 to 24 hours should be continued in severely immunocompromised patients who are at risk for relapse.

Selected patients may receive oral ganciclovir for maintenance therapy, when available. Historically, ganciclovir 250- and 500-mg capsules and oral solution for oral administration were used for maintenance. These oral formulations of ganciclovir are rarely used now, since the introduction of valganciclovir oral capsules and solution, which provide superior bioavailability over oral ganciclovir.

The usual recommended dose for oral ganciclovir in adults was 1000 mg three times daily or, alternatively, 500 mg administered six times daily. The pediatric dose for maintenance oral therapy is not established. The duration of maintenance therapy should be individualized for each patient, but such therapy usually lasts through the period of greatest risk, such as rejection or immune suppression, or may be lifelong, as in patients with AIDS. Some patients who experience CMV disease, such as solid-organ transplant recipients with minimal immune suppression and minimal or no rejection, will respond dramatically to induction therapy and will not require long-term maintenance therapy.

A dose of 6 mg/kg administered every 12 hours for 6 weeks is recommended to treat newborns with moderate to severe congenital CMV disease.^{336,338,360,631} This dose appears to be adequate for term newborns and premature newborns as young as 32 weeks' gestation, provided renal function seems to be normal for age. The dose for extremely premature newborns is not known and should be individualized according to the clinical judgment of the infectious diseases specialist. Oral valganciclovir is also recommended in newborns who are able to take and absorb oral medications for 6 months for treatment of congenital CMV disease.

Preemptive therapy, 5 mg/kg per dose administered every 12 hours, is initiated when virologic markers for active, invasive infection, such as positive cultures for CMV from bronchoalveolar lavage samples or the presence of CMV DNAemia or antigenemia, are identified by routine virologic surveillance.^{548,553} After an induction period of 7 to 14 days, maintenance therapy usually is continued for 100 to 120 days after transplantation or longer if the patient remains at high risk for relapse of CMV disease. Prophylaxis with ganciclovir is administered immediately before transplantation and for a defined period after transplantation in patients who are at high risk, such as those who are CMV seropositive before transplantation and those who receive marrow or solid-organ transplants from a CMV-seropositive donor.^{72,159,203,217,507,511,615,616}

Patients who do not respond to induction therapy, who relapse or progress during maintenance therapy with ganciclovir, or who have rising plasma levels of CMV DNA may have a resistant strain of CMV. Antiviral resistance has been documented in immunocompromised patients and newborns.¹⁸⁶ The addition of another antiviral with different mechanisms of action, such as foscarnet or cidofovir, may be beneficial. Maribavir may also be available by compassionate use in selected patients. If clinical or virologic responses still are not maintained, the possibility of a multiply resistant CMV strain should be considered. Patients with disseminated adenovirus disease have received doses of 5 mg/kg every 12 hours for 14 or more days, but clinical benefit has not been proved.⁴³⁰

Adverse effects. Adverse effects of ganciclovir can be both local and systemic. Local reactions, such as phlebitis, irritation, blistering, and ulceration at or around the infusion site, can occur and usually are attributed to the alkaline pH (pH 11) of the intravenous solution. Local

*References 73, 131, 159, 217, 218, 266, 279, 414, 511, 615.

†References 81, 108, 117, 148, 153, 167, 479, 480, 505, 507, 508.

reactions can be minimized by paying careful attention to the infusion site or by administering the antiviral agent through a central venous catheter. The most common systemic toxicity associated with ganciclovir administration is dose-dependent, reversible neutropenia, which occurs in one-third to one-half of patients (adults, children, and newborns) who receive this antiviral for longer than 2 weeks.^{131,179} Thrombocytopenia also can occur, most often in patients with AIDS who are receiving other antiviral agents, including antiretrovirals.²⁷⁷ If the neutropenia is severe (absolute neutrophil count <500/mm³), ganciclovir administration should be halted temporarily until the neutrophil count recovers. Ganciclovir then may be readministered, if it is still clinically indicated, at the same or half the original dose while the patient is carefully monitored for recurrence of the neutropenia. Some experts have used recombinant granulocyte-macrophage colony-stimulating factor successfully to treat ganciclovir-induced neutropenia.²⁴² Anemia associated with ganciclovir administration is an unusual occurrence. Other adverse effects associated with ganciclovir include CNS disturbances, such as headache, behavioral changes, psychosis, seizures, and coma; mild nephrotoxicity with azotemia; liver dysfunction with elevated transaminases; and rash. Ganciclovir also is mutagenic, carcinogenic, and immunosuppressive. In addition, preclinical animal studies showed reproductive toxicity, with teratogenicity, embryotoxicity, and testicular atrophy.¹⁷⁹ Long-term studies in children who received ganciclovir as newborns are being conducted to determine the long-term effects of ganciclovir administration, if any. To date, none has been reported in case reports or case series. Also, caretakers who prepare and administer ganciclovir to patients should take precautions to minimize direct exposure to the antiviral agent.

Valganciclovir

Spectrum of Activity

Valganciclovir (L-valine, 2-[(2-amino-1,6-dihydro-6-oxy-9H-purin-9-yl)methoxy]-3-hydroxypropyl ester) is a prodrug of ganciclovir and therefore has the same selective spectrum of activity as ganciclovir against herpesviruses, especially CMV, as well as limited activity against adenoviruses and HBV.

Mechanism of Action and Resistance

Valganciclovir is the L-valyl ester (prodrug) of ganciclovir.³⁹⁴ It is metabolized rapidly in the body to ganciclovir. Ganciclovir then is monophosphorylated by viral protein kinase (coded for by UL97 genes) in CMV-infected cells and further phosphorylated to the active form ganciclovir triphosphate by cellular kinases. Viral DNA synthesis is inhibited by ganciclovir triphosphate (see [ganciclovir](#) for details). Isolates of CMV become resistant to valganciclovir by mutations in UL97, the viral kinase gene, or in UL54, the viral DNA polymerase gene. Mutations in UL97 confer resistance to ganciclovir and therefore to valganciclovir, whereas mutations in UL54 confer double or triple resistance to ganciclovir, foscarnet, and cidofovir. Mutations in both genes can produce highly resistant strains of CMV.

Pharmacokinetics

Valganciclovir is well absorbed after oral administration and is rapidly hydrolyzed in the intestine and liver to ganciclovir.⁴⁶⁴ The bioavailability of valganciclovir is high, approximately 60% (vs. 6–9% for ganciclovir), and an oral dose of 900 mg administered to adults produces ganciclovir blood levels equivalent to a 5-mg/kg dose administered intravenously.^{75,317,394} Absorption is enhanced significantly with the ingestion of food, so physicians recommend that valganciclovir be taken with food or meals. The drug is excreted by the kidneys, and renal insufficiency produces prolonged excretion and a longer half-life (see [ganciclovir](#)). Oral valganciclovir solution has been administered to neonates and infants up to 6 months of age, at a dosage of 16 mg/kg per dose (range of 15–18 mg/kg per dose) every 12 hours, adjusted for renal function, if necessary. A dosing algorithm for pediatric patients, including infants younger than 4 months, based on body surface area and renal function, instead of weight, may also be used.⁷⁰ Valganciclovir is 41% bioavailable and provides stable and constant plasma concentrations and antiviral effects comparable to intravenously administered ganciclovir.^{340,518} Pharmacokinetic studies have shown stable and effective antiviral plasma

concentrations (mean trough, 0.51 µg/mL; and mean 2-hour peak, 3.81 µg/mL) and penetration into the CSF of infants.^{378,435} Valganciclovir oral solution should be adjusted monthly for weight gain and also may be mixed with small amounts of formula or breast milk in a measured syringe to facilitate newborns and infants to take the antiviral.

Clinical Indications, Dosage, and Adverse Effects

Valganciclovir is available in 450-mg tablets, and the usual adult dose is 900 mg (two 450-mg tablets) twice daily for 14 days (induction therapy), followed by a maintenance dose of 900 mg administered once daily.³⁹⁴ An oral solution (50 mg/mL concentration) is also licensed and available.³³⁵ Valganciclovir is licensed for induction and maintenance treatment of CMV retinitis in immunocompromised patients, but clinical trials have shown that valganciclovir is beneficial to a variety of patients with a number of different CMV infections.³⁹⁴ Antiviral prophylaxis or preemptive treatment for CMV DNAemia with valganciclovir for 100 to 200 days after transplantation in high-risk transplant recipients significantly reduces the incidence of CMV disease and improves graft survival.⁶¹⁷ Oral valganciclovir suppression in pediatric kidney transplant recipients for up to 200 days has been shown to be effective and to have a favorable safety profile.⁵⁸⁶

Treatment of newborns with symptomatic congenital CMV infection with oral valganciclovir (15–18 mg/kg per dose every 12 hours) appears beneficial, similar to intravenous ganciclovir benefits, providing improved head circumference, improved developmental milestones, and reduced risk for hearing loss and progression. A randomized clinical trial comparing 6 weeks versus 6 months of treatment in congenitally infected newborns has recently shown the longer 6-month duration of treatment to be more beneficial.¹¹ In some centers, treatment up to 12 months of age has shown benefit for prevention of hearing loss progression.¹⁴ There are case reports of the use of valganciclovir or ganciclovir to treat newborns with asymptomatic congenital CMV with hearing loss, and some experts have advocated treatment of selected newborns with congenital hearing loss, especially if they have high or prolonged viral DNA levels in plasma.³²⁶ However, conclusions about the efficacy of such treatment cannot be made from these reports at this time and await results of randomized clinical trials.^{354,622} Currently, antiviral treatment of symptom-free newborns with congenital CMV and normal hearing is not recommended.

As with ganciclovir, if a patient treated with valganciclovir experiences progression of disease or recurrence during maintenance therapy, a resistant strain of CMV should be considered a possibility and antiviral treatment adjusted accordingly.³¹² Adverse effects associated with the oral administration of valganciclovir include diarrhea and dose-dependent, reversible neutropenia.³⁹⁴

Neonates with congenital CMV disease treated with oral valganciclovir experience neutropenia approximately 19% of the time. Also reported has been a mild elevation of liver enzymes, as well as possible changes in patterns of sleeping or gastrointestinal upset in some infants.

Foscarnet

Spectrum of Activity

Foscarnet (phosphonoformic acid or trisodium phosphonoformate hexahydrate) is a pyrophosphate analogue that selectively inhibits herpesviruses⁴⁴⁸ (Fig. 239.10). It also has activity against HIV and HBV.^{30,176} At concentrations of 100 to 300 µmol/L, CMV is inhibited; whereas slightly lower concentrations (80–200 µmol/L) inhibit HSV types 1 and 2, VZV, EBV, and HHV-8.⁴⁴⁸ Concentrations between 20 and 200 µmol/L appear to inhibit HBV. Foscarnet also inhibits most acyclovir-resistant HSV and VZV strains and most ganciclovir-resistant CMV strains.^{195,389,498} Combinations of ganciclovir and foscarnet are

Foscarnet

FIG. 239.10 Structure of foscarnet.

synergistic against CMV, and combinations of zidovudine and foscarnet appear to be synergistic against HIV.^{176,389} At high concentrations (500–1000 $\mu\text{mol/L}$), foscarnet inhibits cellular DNA synthesis in uninfected cells.¹⁰⁶

Mechanism of Action and Resistance

Foscarnet is not a nucleoside analogue, and it does not require phosphorylation or any other form of intracellular metabolism to be activated. Rather, it is a pyrophosphate analogue that directly inhibits viral and cellular DNA polymerase.^{132,145} Selective viral inhibition is accomplished by noncompetitive and reversible blocking of the pyrophosphate binding site of the viral polymerase, in much lower concentrations than it inhibits cellular DNA polymerases. Because foscarnet does not require phosphorylation by viral TK or other kinases, it inhibits TK-deficient and altered strains of HSV and VZV that are resistant to acyclovir as well as UL97 phosphotransferase mutants of CMV that are resistant to ganciclovir. However, strains of herpesviruses of all types that are resistant to acyclovir or ganciclovir by mutation of the viral DNA polymerase gene are also resistant to foscarnet.^{31,500}

Pharmacokinetics

Intravenous administration of 60 mg of foscarnet every 8 hours to adults produces plasma levels of 450 to 575 $\mu\text{mol/L}$; 90 mg administered every 12 hours produces plasma levels of 420 to 746 $\mu\text{mol/L}$.^{145,498} CSF levels are usually approximately 60% of plasma levels, and vitreous concentrations in the eye are the same as or slightly higher than plasma levels.²⁶² Most (80%) of the dose of foscarnet is eliminated unmetabolized from the body through the kidneys, and plasma clearance decreases if renal function is impaired. The remaining 20% appears to be deposited in teeth and bone, where it accumulates and remains for months. The drug is removed by hemodialysis, but not appreciably by peritoneal dialysis.^{8,386} Oral foscarnet has poor bioavailability (<10%) and causes diarrhea, and it is unlikely to be available for patient use.⁴⁴⁷ Pharmacokinetic data in infants and children have not been published. However, preclinical studies showed that deposition of foscarnet in teeth and bones is greater in younger than in older animals.

Clinical Indications, Dosage, and Adverse Effects

Clinical indications. Foscarnet is licensed for both induction and maintenance treatment of CMV retinitis in immunocompromised patients and for treatment of mucocutaneous disease caused by acyclovir-resistant HSV.* Foscarnet also may be of benefit in patients with varicella or zoster caused by acyclovir-resistant VZV.⁴⁹⁸ Because the combination of foscarnet and ganciclovir appears to be synergistic in vitro, immunocompromised patients who experience progression or relapse of CMV disease while receiving therapy with one or the other antiviral agent may benefit from combination therapy in some instances.^{25,156,195,309} Foscarnet also may be used for the treatment or prophylaxis of serious or life-threatening CMV disease when ganciclovir is contraindicated or otherwise deemed clinically undesirable because of its myelosuppressive effects.^{25,485,623} The antiretroviral properties of foscarnet, when it is combined with other antiviral agents, also may be beneficial in patients with HIV infection or AIDS.^{48,310,456,560,561}

Dosage. Treatment with foscarnet usually is divided into two phases, induction and maintenance. The usual dosage of foscarnet for induction therapy is 60 mg/kg per dose administered intravenously every 8 hours for 3 weeks; maintenance therapy is 90 to 120 mg/kg per day administered indefinitely or through the period of risk.³²² The dose of foscarnet should be given slowly, during the course of 2 hours (or no faster than 1 mg/kg per minute), to reduce renal toxicity. Creatinine clearance should be used to adjust dosage regimens in patients with renal insufficiency or renal failure. Published experience on the use of foscarnet in pediatric patients is limited, but undoubtedly, certain pediatric patients benefit from receiving foscarnet therapy.⁵⁹⁶ In these cases, the same per-kilogram dosage regimens can be used for most patients. Prehydration with saline and the use of probenecid with each dose are recommended in some patients to reduce renal toxicity.

Cidofovir

FIG. 239.11 Structure of cidofovir.

Adverse effects. Foscarnet is associated with serious adverse effects and should be used only after thorough consideration of the risks and benefits involved.^{106,145} Renal toxicity with azotemia, proteinuria, crystaluria, renal tubular acidosis or necrosis, and interstitial nephritis can occur in as many as a third of patients who receive foscarnet.^{143,315} Renal toxicity generally occurs after the first week of therapy and usually is reversible. The risk for the development of renal toxicity is increased if the drug is given by rapid infusion or administered in high doses, if the patient is dehydrated, or if other nephrotoxic drugs are administered concomitantly with foscarnet.⁴³⁹ Hydration, including saline loading, and administration of each dose during the course of at least 2 hours appear to reduce the risk for development of renal toxicity. Foscarnet binds divalent metal ions such as calcium in the body, and metabolic abnormalities, including hypocalcemia and hypercalcemia (total or ionized), hypophosphatemia and hyperphosphatemia, hypomagnesemia, and hypokalemia, may occur in approximately one-third of patients who receive foscarnet.³⁰⁷ Symptoms of these acute metabolic abnormalities include perioral tingling, numbness or paresthesias of the limbs, and, if severe, seizures, tetany, and cardiac dysrhythmias. Administration of the dose during the course of at least 2 hours also reduces the risk for development of metabolic abnormalities. Foscarnet also can be deposited and concentrate in bone, with as yet unclear long-term consequences.¹⁴⁵ CNS side effects also occur in approximately one-fourth of patients and include headache, tremor, seizures, and behavioral changes. Abnormal liver function test results have been noted, and high urinary concentrations of foscarnet may produce painful genital ulcerations and rash in some patients.^{267,539} Preclinical studies showed foscarnet to be mutagenic and associated with anomalies of skeletal development in young animals.¹⁴²

Cidofovir and Brincidofovir

Spectrum of Activity

Cidofovir, (S-1-3-hydroxy-2-[(phosphonomethoxy)propyl]cytosine dihydrate (also known as HPMPC), is an acyclic phosphonate nucleotide analogue of deoxycytidine monophosphate with broad-spectrum in vitro antiviral activity against all DNA viruses, including herpesviruses (HSV types 1 and 2; CMV, EBV, and VZV; and HHV types 6, 7, and 8), adenoviruses, polyomaviruses (JC and BK viruses), papillomaviruses, and poxviruses (vaccinia, variola or smallpox, cowpox, monkeypox, camelpox, and molluscum contagiosum and orf viruses) (Fig. 239.11).^{*} Cidofovir exhibits its most specific and potent antiviral activity against CMV (minimal inhibitory concentration, 0.25 $\mu\text{mol/L}$).^{99,98,154,168} The compound also is very active against VZV (0.79 $\mu\text{mol/L}$), HSV-1 (12.7 $\mu\text{mol/L}$), and acyclovir-resistant, TK-deficient HSV-1 strains (6.24 $\mu\text{mol/L}$).^{275,412,540} Cidofovir inhibits HSV-2 at concentrations of 31.7 $\mu\text{mol/L}$, adenoviruses at 10.8 $\mu\text{mol/L}$, and vaccinia virus at 12.7 $\mu\text{mol/L}$.^{141,220,533} Strains of CMV UL97 mutants that are resistant to ganciclovir are inhibited by cidofovir, and cidofovir in combination with ganciclovir or foscarnet shows synergistic inhibition of CMV in vitro.⁴⁹⁹

*References 145, 156, 309, 365, 386, 456, 500, 519, 520, 596.

*References 18, 98, 99,141, 154, 168, 207, 220, 275, 412, 439, 440, 499, 529, 530, 533, 540, 584.

Brincidofovir (3-hexadecyloxy-propyl-cidofovir [HDP-CDV or CMX001]) is the lipid conjugate of the acyclic nucleoside phosphonate antiviral cidofovir. It is a broad-spectrum antiviral agent active in vitro against double-stranded DNA viruses; these include all the herpesviruses, including acyclovir-resistant herpes simplex virus; adenoviruses; polyomaviruses, including BK viruses; and poxviruses, including variola small pox and vaccinia virus.^{429,450,588} Brincidofovir also may be used to treat ganciclovir-resistant CMV infection, unless the resistance is acquired through UL54 mutation. In addition, it may have in vitro activity against RNA viruses, such as Ebola virus, in its lipid moiety form.^{189,409}

Mechanisms of Action and Resistance

Cidofovir inhibits the replication of CMV and other viruses by selective inhibition of viral DNA polymerase.^{99,275,412} The compound is phosphorylated by cellular enzymes to the active form cidofovir diphosphate. Cidofovir diphosphate inhibits both viral and cellular DNA polymerase; however, because the concentration necessary to inhibit cellular DNA synthesis is hundreds of times higher than that needed to inhibit viral DNA synthesis, cidofovir appears to selectively inhibit viral DNA synthesis at concentrations safely administered to humans. Cidofovir diphosphate has a long intracellular half-life that provides prolonged and persistent antiviral activity and allows infrequent dosing regimens in humans.^{188,276,540} Because the compound does not require TK for initial phosphorylation, it is active against TK-deficient and TK-altered acyclovir-resistant HSV strains.⁴¹² Resistance to cidofovir is unusual but can occur by mutations in viral DNA polymerase genes (codons 375 to 540 and possibly 978 to 988), most likely in patients who have received prolonged or repeated periods of treatment with ganciclovir or foscarnet. Strains of CMV that are resistant to cidofovir are also usually resistant to ganciclovir, and occasionally, triple mutants resistant to ganciclovir, foscarnet, and cidofovir occur.^{154,574}

Brincidofovir is cleaved of its lipid moiety to be cidofovir, which is then converted through phosphorylation intracellularly into the active antiviral cidofovir diphosphate, which inhibits viral DNA polymerase by serving as an alternate substrate and results in inhibition of DNAsynthesis, for action against DNA viruses. However, for action against the RNA virus Ebola virus, intracellular phosphorylation may not be necessary for antiviral inhibition.

Pharmacokinetics

After an intravenous infusion of 5 mg/kg of cidofovir, peak plasma levels range from 11.6 to 26.1 µg/mL, with the latter occurring after administration of probenecid.^{133,499,574} The plasma half-life is 2 to 3 hours, but the intracellular half-life is prolonged (between 17 and 65 hours).⁵⁴⁰ CSF penetration by cidofovir is not well studied, but in at least one patient, the drug did not appear to cross the blood-brain barrier in detectable amounts. After topical administration to the eye or intact skin, systemic absorption is low, with peak plasma levels usually less than 0.5 µg/mL.^{357,358} However, patients with abraded or denuded skin may have significant absorption.⁵² The systemic absorption that occurs after intralesional or subcutaneous administration is not well characterized at this time. Intravitreal administration produces sustained antiviral effects in animal models.¹⁸⁸ Cidofovir is not well absorbed orally, with less than 5% bioavailability. However, bioavailable alkoxyalkyl esters of cidofovir are in development and may lead to an oral compound in the near future.³³¹ Aerosolized cidofovir also is being studied in animal models and appears to deliver high concentrations of antiviral to the lungs.⁷² Cidofovir is eliminated through the kidney by glomerular filtration and active tubular secretion, and more than 90% of the original dose can be recovered unchanged in urine.

Brincidofovir, because of its lipid conjugation, has high oral bioavailability, higher intracellular concentrations of active drug, lower plasma concentrations of cidofovir, and increased antiviral potency against double-stranded DNA viruses.¹⁹⁰ Oral dosing of 4 mg/kg per dose administered every week or 2 mg/kg per dose twice weekly, or adult dosing of 100 to 200 mg per week, exceed inhibitory concentrations of most double-stranded DNA viruses of medical importance in humans. After 100 mg and 200 mg oral doses, mean trough levels of brincidofovir were between 10 to 17 ng/mL and 10 to 30 ng/mL, respectively, under fasting conditions. An intravenous formulation of brincidofovir is also under early clinical development.

Clinical Indications, Dosage, and Adverse Effects

Clinical indications. Cidofovir is licensed for induction and maintenance treatment of CMV retinitis in immunocompromised adults with AIDS.^{499,562} Clinical trials have shown that cidofovir significantly delays progression of CMV retinitis in previously untreated patients as well as in those who previously failed to respond to or were intolerant of foscarnet or ganciclovir therapy.^{357,358,377,469,472,522} Cidofovir also has been shown to be effective for the treatment of CMV infection and disease in marrow and stem cell transplant recipients. In addition, it has been used, in selected patients, for preemptive treatment of CMV infection after marrow and stem cell transplantation.^{93,377,469} One study also showed that cidofovir helped prevent posttransplantation CMV-associated atherosclerosis in rats.⁷⁸ Patients infected with CMV strains resistant to ganciclovir or foscarnet, or both, may benefit from receiving cidofovir treatment.¹⁵⁴ Cidofovir is used by clinicians to treat immunocompromised children with serious CMV disease despite the lack of published experience in children.^{80,90}

Cidofovir has broad-spectrum antiviral activity, and published case reports show that it has been used to treat patients with serious infections caused by a wide variety of DNA viruses. For example, patients with acyclovir- and foscarnet-resistant HSV infection have been treated successfully with topical and systemic cidofovir.^{79,348,356,358} It also may be effective in treatment of selected patients with acyclovir-resistant VZV infections.⁵³³ Moreover, one report showed that treatment with cidofovir and anti-CD20 monoclonal antibody was associated with remission and regression of posttransplantation EBV-associated lymphoproliferative disease.²⁴¹ The use of cidofovir to treat patients with AIDS and HHV-8 viremia and disease also has been reported.^{65,401} Human papillomavirus-induced epithelial cell proliferation may be responsive to treatment with topical and intralesional administration of cidofovir.⁵⁵⁷ Several small, uncontrolled case series have described the successful use of cidofovir to treat juvenile laryngeal papillomatosis, hypopharyngeal and esophageal papillomatous lesions, anogenital condylomas, and cervical intraepithelial neoplasia.^{21,100,454,516,538,627} Furthermore, intravenous and intralesional therapy with cidofovir has been used to treat individual patients, including children, with refractory disseminated respiratory papillomatosis of the lung.^{21,378,388} Human BK polyomavirus-associated acute hemorrhagic cystitis in immunocompromised patients has been treated with cidofovir, with varying results.^{37,178} Case reports and small clinical trials evaluating cidofovir treatment in patients with progressive multifocal leukoencephalopathy who have AIDS or other immunocompromising conditions have not shown consistent benefit in survival or sustained improvement in neurologic status.^{19,109,204,292,428,478,501,519} Successful cidofovir treatment of adenovirus disease in marrow and stem cell transplant recipients has been published in reports of case series, with the best results noted in patients in whom the disease was localized and treatment was initiated early.^{64,206,278,367,400,486} Controlled clinical trials evaluating eye drops containing an investigational topical solution of cidofovir to treat patients with acute keratoconjunctivitis caused by adenovirus have not shown consistent benefit in the doses used.^{270,271} Poxviruses are inhibited by cidofovir in concentrations safely achievable in humans, and at least one case report of successful treatment of orf (ecthyma contagiosum) has been published.^{17,207} In addition, in vitro and animal model data suggest that cidofovir may be effective as short-term, postexposure prophylaxis of smallpox and other related poxvirus infections in humans as well as in the treatment of complications that may occur after inoculation with smallpox (vaccinia-like) vaccine.^{18,98,99,141,154,499,486} However, no clinical trials in humans to evaluate the efficacy of cidofovir for the treatment of poxvirus infections have been published.⁴⁴¹

Brincidofovir remains investigational at this time, and phase II and phase III clinical trials in adults and pediatric patients are underway (<https://clinicaltrials.gov>). In addition, more than a thousand patients have been administered brincidofovir under clinical trial or compassionate use, and case reports have shown safety and efficacy for a variety of viral infections in immunocompromised hosts. The clinical efficacy of brincidofovir for prophylaxis of CMV has shown significant benefit³⁹⁵; however, for treatment of CMV and adenovirus infections, in particular, it has not shown overwhelmingly positive results in clinical trials to date.

Dosage. The usually recommended dose for induction therapy with cidofovir is 5 mg/kg given as an intravenous infusion during the course

of 1 hour administered once weekly for 2 consecutive weeks. Some clinicians suggest a reduced dosage regimen of 1 mg/kg administered three times weekly to reduce the risk for renal toxicity.²⁷⁸ Maintenance therapy usually is administered as 1-hour infusions of 5 mg/kg once every 2 weeks to complete a total of at least five doses. These doses should be decreased to 1 to 3 mg/kg if renal insufficiency is present and discontinued if significant elevation of serum creatinine concentration or proteinuria occurs. Probenecid should be administered orally with each dose of cidofovir, 3 hours before and then 2 and 8 hours after completion of the intravenous infusion. Prehydration with normal saline before each infusion also is recommended. Topical preparations of eye drops containing 0.2% to 1% cidofovir and creams containing 1% cidofovir are being investigated.^{271,270} The usual concentration used for intravesical injection is 2.5 mg/mL.^{340,388}

Brincidofovir oral dosing in phase II and III clinical trials has been 2 mg/kg per dose twice weekly or 4 mg/kg per dose once weekly for adults and children. For individuals weighing more than 50 kg, 100 mg twice weekly or 200 mg once weekly has been used. The usual maximum dose per week has been 4 mg/kg per dose or 200 mg/dose weekly. Some clinical trials have used 40 mg/kg once-weekly dosing, with escalations to 100 mg and 200 mg doses weekly. Brincidofovir appears to be well absorbed under fasting conditions with a time to maximum plasma drug concentration proportional to the dose administered and ranging from 2 to 3 hours in adults. Half-life of the drug increases as the dose increases, with ranges from 6 to 24 hours. Brincidofovir is not detected in urine, but its elimination product cidofovir is detected after brincidofovir administration. No pharmacokinetics is available yet for neonates and infants; however, dose escalation pharmacokinetic studies evaluating 0.25, 0.5, 1, and 2 mg/kg per dose may be conducted in the future. Dosing in renal impairment usually does not require adjustment, based on current information. Dosing after dialysis is 1 mg/kg one to two times per week given after dialysis. There are no recommendations for adjustment in hepatic impairment. At this time, no information on use of brincidofovir in pregnancy or excretion in breast milk of breast-feeding women is available.

Adverse effects. Cidofovir is nephrotoxic and produces clinically apparent proximal tubular dysfunction, including Fanconi syndrome and acute renal failure, in as many as half the patients who receive the drug.^{411,499} Early laboratory signs of renal toxicity include proteinuria, glycosuria, azotemia, and metabolic acidosis. Therefore patients receiving cidofovir should have a urinalysis and serum tests for renal function performed before taking each dose. The risk for development of renal toxicity can be reduced but not eliminated by probenecid and saline prehydration. Moreover, renal toxicity is more likely to occur if other nephrotoxic agents, such as aminoglycosides, amphotericin B, or foscarnet, are administered concurrently with cidofovir.⁶²⁹ In clinical trials of patients with AIDS, administration of cidofovir also was associated with neutropenia. Ocular toxicity, including ocular hypotony (decreased intraocular pressure) and anterior uveitis and iritis, also has been reported in patients receiving cidofovir therapy.⁵ Therefore frequent monitoring by an ophthalmologist, including measurement of intraocular pressure, is recommended for patients receiving cidofovir therapy. Intravitreal administration of cidofovir has produced uveitis, vitreitis, reduced intraocular pressure, and loss of vision.^{341,436} Local or topical treatment with cidofovir may produce local reactions in the skin.

Brincidofovir has significant gastrointestinal side effects, including nausea and diarrhea. Diarrhea is especially common, reported in up to 70% of recipients in the higher range dosing, and is potentially serious in nature. Compared with cidofovir, brincidofovir has little or no nephrotoxicity, although isolated case reports of reversible nephrotoxicity have emerged.¹⁸⁰

Information on drug interactions of brincidofovir is lacking at this time.

Maribavir and Letermovir

Spectrum of Activity and Mechanisms of Resistance

Maribavir (1263W94, VP-41263) and letermovir (AIC246, MK 8228) are oral investigational antivirals with potent activity solely against CMV.⁶⁶

Maribavir is a benzimidazole riboside compound (benzimidavir) with potent activity primarily against CMV documented. It competes with adenosine triphosphate (ATP) for binding to pUL97, does not require

intracellular phosphorylation, and is independent of pUL54. Maribavir directly inhibits UL97 kinase, an early viral gene product involved in viral DNA elongation, packaging, and egress or shedding of viral capsids from viral nuclei. It is active against ganciclovir-resistant CMV.

Resistance to maribavir may develop on therapy, especially if the patient has documented high viral load at the start of treatment with maribavir.^{288,514} Various mutations have been shown to confer maribavir resistance by modifying the UL97 ATP binding site. The UL97 mutations elicited by ganciclovir and maribavir are different, but cross-resistance can occur if a single p-loop mutation occurs. CMV isolates that are resistant to maribavir usually remain susceptible to ganciclovir (and vice versa). Because maribavir inhibits UL97, it will impair phosphorylation of ganciclovir; therefore these two antivirals should not be coadministered at the same time in serious CMV infections. Maribavir and foscarnet, however, have been combined successfully in selected situations.

Letermovir is a viral terminase complex inhibitor with a potent, yet narrow, spectrum of antiviral activity only against human CMV. It has no activity against any other viruses. It has a novel mechanism of action by inhibiting CMV DNA synthesis at a late step by targeting the UL56 subunit of the terminase enzyme complex. It may have activity against CMV strains resistant to ganciclovir, foscarnet, and cidofovir and does not exhibit cross-resistance with other antiviral drugs. It is the protocol viral terminase complex inhibitor and the most advanced one in clinical development at this time.

High-grade resistance mutations in the UL56 terminase gene are readily selected in vitro under letermovir. In addition, in phase II prophylaxis trials, emergence of UL56 mutation V236M in the amino acid region 230–270 was associated with clinical resistance.^{102,215,374}

Pharmacokinetics

Maribavir demonstrates rapid absorption after oral administration, linear pharmacokinetics, and in vivo anti-CMV activity in humans. Mean oral availability in humans ranges 25% to 40%, and it can be recovered in the urine. Peak plasma levels occur approximately 1 to 3 hours after oral administration. There is minimal accumulation of the drug at steady state.³⁸⁵

Letermovir demonstrates rapid absorption after oral administration. Doses may need to be adjusted in patients with renal and hepatic impairment.

Clinical Indications, Dosage, and Adverse Effects

Clinical indications. Maribavir remains investigational, and clinical trials are evaluating how it may be used to treat ganciclovir-resistant CMV infections in immunocompromised patients.¹⁶⁴ However, because it does not penetrate the CSF reliably, if there is a suspicion of or risk for CMV CNS disease, maribavir should not be used for treatment of CMV meningoencephalitis.

Letermovir has been investigated in clinical trials for prevention and treatment of CMV in immunocompromised hosts. Its lack of significant cross-resistance with other anti-CMV antivirals and its lack of myelosuppression make it a favorable option for clinical trials. Its clinical indication has not yet been determined, but it may be used as an antiviral for CMV-specific primary prophylaxis in allogeneic hematopoietic stem cell transplant recipients.⁹⁷

Dosage. Maribavir is an oral antiviral agent. It has been administered in clinical trials in doses ranging from 300 to 600 mg/day up to 1200 to 2400 mg/day. Most trials have used 400 mg twice daily for 10 days in clinical trials of adults.

Letermovir is also an oral antiviral agent. It has been administered in clinical trials in doses ranging from 40 mg twice per day to 80 mg daily to as high as 320 mg daily in adults. Based on early pharmacokinetic trials, daily doses of 120 mg or 240 mg appear to achieve desirable levels without side effects.⁹⁷ No pediatric, neonate, or infant pharmacokinetic data are available at this time.

Adverse effects. Maribavir commonly causes disturbances in taste, but has not demonstrated any other significant side effects to date in clinical trials.

Letermovir appears safe in clinical trials based on information to date, with the only significant side effect noted being gastrointestinal symptoms.

Invasive fungal infections are important causes of morbidity and mortality in children with severe underlying illnesses. These infections remain difficult to diagnose and can be rapidly fatal. As a consequence, early and appropriate antifungal chemotherapy is pivotal for successful management and survival. For decades, options for antifungal chemotherapy were limited to amphotericin B deoxycholate (D-AmB) with or without the addition of flucytosine. The 1990s, however, witnessed major progress through the introduction of the antifungal triazoles fluconazole and itraconazole and the development of less toxic formulations of amphotericin B. More recent advances include the advent of novel, potent, and broad-spectrum antifungal triazoles and the clinical development of echinocandins, a distinct class of antifungal agents that target the fungal cell wall (Fig. 240.1). This chapter is devoted to the clinical pharmacology of systemic antifungal agents; emphasis is placed on pharmacokinetics, dosing, and safety in pediatric age groups.

AGENTS FOR TREATMENT OF INVASIVE MYCOSES

Polyene Antibiotics

Amphotericin B Deoxycholate

First isolated in the 1950s as a natural product of a soil actinomycete,²²⁸ amphotericin B belongs to a family of approximately 200 polyene macrolide antibiotics and consists of seven conjugated double bonds, an internal ester, a free carboxyl group, and a glycoside side chain with a primary amino group (Fig. 240.2). The compound is amphoteric (capable of reacting as either an acid or a base), is not orally or intramuscularly absorbed, and is virtually insoluble in water. For parenteral use, amphotericin B has been solubilized with deoxycholate as a micellar suspension, and this formulation has been produced for more than 50 years and is available in several generic forms.⁵² Current data indicate that these formulations are comparable in activity to the original deoxycholate formulation.⁵¹¹

Mechanism of action. Amphotericin B, similar to other polyenes, acts primarily by binding to ergosterol, the principal sterol in the cell membrane of most fungi. This interaction with ergosterol results in the formation of ion channels, loss of protons and monovalent cations, depolarization, and concentration-dependent cell death. Although with less avidity, the compound also binds to cholesterol, the main sterol of mammalian cell membranes; this action accounts for most of the toxicities associated with this drug. A second mechanism of action of amphotericin B may involve oxidative damage of the cell through a cascade of oxidative reactions linked to its own oxidation, with formation of free radicals or an increase in membrane permeability. In addition to its antifungal activity, amphotericin B and its lipid formulations differentially augment innate host defense mechanisms against fungal pathogens.^{86,167,252,601,602}

Antifungal activity. Amphotericin B has a broad spectrum of antifungal activity that includes most fungi pathogenic in humans. True microbiologic resistance to antifungal polyenes has been associated with qualitative or quantitative differences in the sterol composition of the cell membrane, but this resistance also may be related to increased catalase activity with decreased susceptibility to oxidative damage.²⁵² Resistance to amphotericin B remains uncommon in *Candida* spp. other than *Candida lusitanae*, *Candida guilliermondii*, and *Candida lipolytica*. Some isolates of *Candida glabrata*, *Candida parapsilosis*, and *Candida tropicalis* also may be resistant to amphotericin B.^{662,685,720} *Aspergillus terreus*^{313,623} and some of the emerging pathogens such as *Trichosporon asahii*^{15,691,692} *Fusarium* spp.,^{84,543} *Scedosporium apiospermum*,^{639,694} *Lomentospora (Scedosporium) prolificans*,^{63,405} and certain dematiaceous fungi²⁵⁹ may be completely resistant to safely achievable

serum concentrations of amphotericin B. Acquisition of secondary resistance is an uncommon occurrence and has not been a clinical problem.²⁵¹

Pharmacodynamics. In time-kill studies, amphotericin B displays concentration-dependent fungicidal activity against susceptible *Candida albicans*, *Cryptococcus neoformans*, and *Aspergillus fumigatus*.^{341,342,538} In addition to its concentration-dependent fungicidal dynamics, a prolonged postantifungal effect (PAFE) of amphotericin B of up to 12 hours' duration has been demonstrated in *C. albicans* and *C. neoformans*.^{188,648} Studies in laboratory animals support the concentration-dependent kill kinetics of amphotericin B in vitro. In neutropenic pharmacokinetic and pharmacodynamic mouse models of disseminated candidiasis and pulmonary aspergillosis, peak plasma concentration (C_{max})/minimal inhibitory concentration (MIC) was the parameter that provided the best correlation with outcome as measured by the residual organismal burden in tissue.^{27,718} These laboratory findings indicate that single daily doses rather than continuous infusion will be most effective. Therefore, the dosage of amphotericin B should not be uncritically reduced, and infusion for durations longer than that recommended by the manufacturer should be avoided.

Pharmacokinetics. After intravenous administration, amphotericin B rapidly dissociates from its carrier deoxycholate and becomes highly protein bound before distributing into tissues.¹¹⁸ The disposition of the compound follows a three-compartment model, with rapid initial clearance from plasma followed by a biphasic pattern of elimination with a β half-life of 24 to 48 hours and a prolonged terminal (γ) half-life of 15 days or more.⁴⁰ Tissue levels of amphotericin B in laboratory animals are highest in liver, spleen, bone marrow, kidney, and lung; concentrations in body fluids other than plasma are generally low.^{314,376} However, despite mostly undetectable concentrations in the cerebrospinal fluid (CSF) and comparatively low concentrations in brain tissue across all species, amphotericin B is effective in the treatment of fungal infections of the central nervous system (CNS). After administration of a single dose of 0.6 mg/kg to adult human volunteers, two-thirds of the parent was excreted unchanged in the urine (20.6%) and feces (42.5%) with more than 90% accounted for in mass balance calculations at 1 week, and no metabolites were observed by HPLC or mass spectrometry.^{53,54,140,548} Accordingly, adjustment of dose is not necessary in patients with unrelated renal or hepatic dysfunction.

Reported pharmacokinetic data in pediatric age groups are characterized by a high interindividual variability, which may be related to differences in underlying diseases and modes of administration (Table 240.1).^{44,61,351,470,615} However, infants and children appear to clear the drug from plasma more rapidly than do adults, as indicated by a negative correlation between age and clearance.^{61,351,469} Because distribution into tissues appears to be the main route of clearance from plasma, the faster clearance in individuals of younger age may be explained by the larger relative volume of parenchymatous organs in contrast to that in adults.⁴⁵⁹ Currently, dosage recommendations for all pediatric age groups do not differ from those in adult patients.

Adverse effects. Infusion-related reactions and dose-limiting nephrotoxicity are major problems associated with the use of D-AmB and often limit successful therapy.⁸³ Infusion-related reactions (i.e., fever, rigors, chills, myalgia, arthralgia, nausea, vomiting, and headaches) are thought to be mediated by the release of cytokines, particularly tumor necrosis factor- α (TNF α) from monocytes in response to the drug.³² These reactions can be noted in as many as 73% of patients prospectively monitored at the bedside.⁵⁸⁴ In a prospective interventional study of pediatric patients with cancer, investigators observed fever, rigors, or both associated with the infusion of D-AmB in 19 of 78 treatment courses (24%).⁴⁷⁰ However, these characteristic adverse effects of

FIG. 240.1 Cellular targets of approved antifungal agents for treatment of invasive mycoses. (Modified from Groll AH, Piscitelli SC, Walsh TJ. Antifungal pharmacodynamics: concentration-effect relationships in vitro and in vivo. *Pharmacotherapy*. 2001;21[suppl 8]:133-148.)

FIG. 240.2 Structural formula of amphotericin B.

TABLE 240.1 Pharmacokinetic Parameters of Amphotericin B Deoxycholate in Pediatric Patients ^a						
Population/Reference	Dosage (mg/kg)	C _{max} (μg/mL)	AUC _{0-∞} (μg/mL/h)	Vd _{ss} (L/kg)	Cl (L/h/kg)	t _{1/2} (h)
Preterm neonates ⁶¹⁵ (n = 5, 0.5–7.5 mo)	1/md	0.96	NA	4.1	0.122	39
Preterm neonates ⁴⁴ (n = 13, 0.06–1.8 mo)	0.5/md	0.96	NA	1.5	0.036	14.8
Infants/children ³⁵¹ (n = 13, 0.08–18 y)	0.5/sd	1.5	NA	0.37	0.026	9.9
Infants/children ⁶¹ (n = 12, 0.3–14 y)	0.68/md	2.9	NA	0.76	0.027	18.1
Infants/children ⁴⁷⁰ (n = 20, 2.2–14.3 y)	0.98/sd	2.43	22.0	0.92	0.039	15.1
Children/adults ¹³ (n = 20, 4–66 y)	1/md	2.9	36	1.1	0.028	39

^aAll values are given as means.
AUC_{0-∞}, Area under the concentration versus time curve from time zero to infinity; Cl, plasma clearance; C_{max}, peak plasma concentration; md, multiple-dose data; NA, not assessed; sd, single-dose data; t_{1/2}, elimination half-life; Vd_{ss}, apparent volume of distribution at steady state.

amphotericin B are observed only rarely in the neonatal setting.³³⁸ In clinical practice, infusion-related reactions associated with amphotericin B therapy may be blunted by slowing the infusion rate but often require premedication with acetaminophen 10 to 15 mg/kg, hydrocortisone 0.5 to 1 mg/kg, or meperidine 0.2 to 0.5 mg/kg.⁶⁸⁵ Less common acute adverse effects are hypotension, hypertension, flushing, and vestibular disturbances; bronchospasm and true anaphylaxis are rare occurrences.²⁵¹ Cardiac arrhythmias and cardiac arrest resulting from acute potassium release may occur with rapid infusion (<60 minutes), especially if the patient has preexisting hyperkalemia or renal impairment.^{95,233,448}

The hallmarks of amphotericin B–associated dose-limiting nephrotoxicity are azotemia, wasting of potassium, and wasting of magnesium. The mechanisms of amphotericin B-induced nephrotoxicity have been recently reviewed.³⁹⁶ Renal tubular acidosis and impaired urinary concentration ability rarely are of clinical significance.^{230,575} Relevant electrolyte wasting occurs in approximately 12% of prospectively monitored patients.⁶⁸⁴ Hypokalemia can be quite refractory to replacement until hypomagnesemia is corrected.⁵⁷⁵ Azotemia is a common occurrence. In a large prospective clinical trial, the baseline serum creatinine rose by more than 100% in 34% of 344 unstratified pediatric

and adult patients receiving D-AmB for empirical therapy of fever and neutropenia.⁶⁸⁴ Azotemia can be exacerbated by concomitant nephrotoxic agents, in particular by cyclosporine and tacrolimus.⁷¹⁶ In series reporting safety data of D-AmB 0.5 to 1 mg/kg in premature neonates, the frequency of azotemia ranged from zero to 15%,^{96,226,338,378,383} a finding indicating that the compound is much better tolerated in this setting than was reported early during its use.⁴³

Nephrotoxicity associated with the use of amphotericin B has the potential to lead to renal failure and dialysis⁷²²; however, azotemia usually is reversible after discontinuation of the drug.^{179,378,685} Avoiding concomitant nephrotoxic agents, appropriate hydration and normal saline loading (3 mEq Na⁺/kg per day)^{32,33,281} may greatly lessen the likelihood and severity of azotemia associated with amphotericin B therapy.

Other potentially relevant adverse effects of amphotericin B include a demyelinating encephalopathy⁴⁶² and normocytic, normochromic anemia associated with low erythropoietin levels after long-term administration.¹⁴¹ Because D-AmB is topically irritating, a central line should be used for infusion, and local instillation of amphotericin B should be considered only in conjunction with expert consultation.

Therapeutic monitoring. Historically, 1-hour postinfusion plasma concentrations of twice the MIC of the fungal isolate have been proposed as targets for treatment of yeast infections.¹⁷⁶ However, monitoring of amphotericin B concentrations in plasma or CSF appears to be of little value because relationships between plasma and tissue concentrations and clinical efficacy or toxicity have not been adequately characterized.²⁵¹

The toxicity of amphotericin B and the practice of normal saline loading warrant close monitoring of serum electrolytes, urea, and creatinine. D-AmB must not be infused in less than 60 minutes and only under particularly careful cardiac monitoring in newborns, as well as in patients with hyperkalemia and renal impairment, where arrhythmias resulting from acute potassium release may develop.^{95,246}

Drug interactions. Drug-drug interactions caused by shared metabolic pathways are unknown for amphotericin B. Hypokalemia may be aggravated by diuretics and corticosteroids, cause rhabdomyolysis, and enhance the effects of nonpolarizing muscle relaxants. Similarly, hypomagnesemia may become especially profound in patients with cancer and chemotherapy-associated nephropathy. Impairment of glomerular filtration by amphotericin B may enhance plasma levels and, thereby, toxicity of many renally cleared drugs, including aminoglycosides, vancomycin, flucytosine, and cyclosporine.²⁵¹ Finally, the simultaneous infusion of granulocytes has been associated with acute

pulmonary reactions,⁷³⁰ and the two interventions should be chronologically separated as much as possible.

Indications. With the exception of resource-limited settings, few indications are left for antifungal treatment of opportunistic mycoses with D-AmB. These indications include candidemia and acute tissue-invasive candidiasis, particularly in neonates, and induction therapy for cryptococcal meningitis; however, in the absence of adequate clinical trials, D-AmB is still a valid option for treatment of severe forms of the endemic mycoses (Tables 240.2 to 240.4). Depending on both the type of infection and the host, the recommended daily dosage ranges from 0.7 to 1 mg/kg per day administered over 2 to 4 hours as tolerated.²⁵¹ Continuous infusion has no pharmacodynamic rationale,^{27,718} no significant impact on renal toxicity,¹⁹⁷ and should not be used.

For empirical antifungal therapy in the persistently febrile neutropenic host, the historical standard dosage has been 0.5 to 0.6 mg/kg per day.^{196,528} Efficacy of prophylactic intravenous amphotericin B in the setting of anticancer therapy has not been documented,²⁵³ and a large, randomized, multicenter study failed to show any preventive benefit of aerosolized amphotericin B in neutropenic patients at high risk for developing invasive mold infections.⁵⁸⁵ However, aerosolized amphotericin B may have a preventive role in patients who have undergone lung transplantation.¹⁶⁹

On principle, treatment should be started at the full target dose, with careful bedside monitoring during the first hour of infusion to allow for prompt intervention for infusion-related reactions.⁶⁸⁵ With the exception of uncomplicated candidemia and induction therapy of cryptococcal meningoencephalitis, the duration of treatment is ill defined for most infections.

Amphotericin B Lipid Formulations

During the late 1990s, three novel formulations of amphotericin B were approved in the United States and most of Europe: AmB colloidal dispersion (ABCD, Amphocil, or Amphotec), AmB lipid complex (ABLC or Abelcet), and a small unilamellar liposomal formulation (L-AmB, AmBisome). Because of their reduced nephrotoxicity in contrast to D-AmB, these compounds allow for the safer delivery of higher dosages of the parent molecule (amphotericin B). However, data from animal models also suggest that higher dosages are required for equivalent antifungal efficacy.^{290,729}

Physicochemical properties and pharmacokinetics. The carriers of the lipid formulations are composed of biodegradable, amphiphilic bilayered membranes in which the hydrophilic heads of the lipid molecules face

outward to shield the hydrophobic tails. The membranes may form either spherical vesicles termed liposomes or bilayered complexes or dispersions with no specific vesicular structure. Incorporated into these water-soluble carriers, amphotericin B becomes soluble in plasma and available for distribution. Each of the lipid formulations of amphotericin B possesses distinct physicochemical and pharmacokinetic properties. All three, however, preferentially distribute to organs of the mononuclear phagocytic system (MPS) and functionally spare the kidney. Whereas the micellar dispersion of ABCD behaves kinetically very similarly to D-AmB, the small unilamellar liposomal preparation has a prolonged circulation time in plasma, achieves strikingly high C_{\max} and area under

the plasma concentration-time curve (AUC) values, and is taken up only slowly by the MPS. In contrast, the large, ribbon-like aggregates of ABLC are efficiently opsonized by plasma proteins and rapidly taken up by the MPS, thus resulting in lower peak plasma and AUC values (Table 240.5).^{249,290} Whether and how the distinct physicochemical and pharmacokinetic features of each formulation translate into different pharmacodynamic properties in vivo is largely unknown. However, experimental head-to-head comparisons of all four formulations of amphotericin B against defined invasive mycoses suggest that important differences exist in antifungal efficacy depending on the agent, dose, type, and site of infection.^{121,243,487}

TABLE 240.5 Physicochemical Properties and Multiple-Dose Pharmacokinetic Parameters of the Four Amphotericin B Formulations^a

Properties and Parameters	D-AmB	ABCD	ABLC	L-AmB
Lipids (molar ratio)	Deoxycholate	Cholesteryl sulfate	DMPC/DMPG (7:3)	HPC/CHOL/DSPG (2:1:0.8)
Mol% AmB	34%	50%	50%	10%
Lipid configuration	Micelles	Micelles	Membrane-like	SUVs
Diameter (μm)	0.05	0.12-0.14	1.6-11	0.08
Dosage (mg AmB/kg)	1	5	5	5
C _{max} (μg/mL)	2.9	3.1	1.7	58
AUC _{0-∞} (μg/mL/h)	36	43	14	713
Vd _{ss} (L/kg)	1.1	4.3	131	0.22
Cl (L/h/kg)	0.028	0.117	0.476	0.017

^aData represent mean values, stem from adult patients, and were obtained after different rates of infusion.

AUC_{0-∞}, Area under the concentration versus time curve from time zero to infinity; CHOL, cholesterol; Cl, plasma clearance; C_{max}, peak plasma concentration; DMPC, dimyristoyl phosphatidylcholine; DMPG, dimyristoyl phosphatidylglycerol; DSPG, distearoyl phosphatidylglycerol; HPC, hydrogenated phosphatidylcholine; SUV, small unilamellar vesicles; Vd_{ss}, apparent volume of distribution at steady state.

Modified from Groll AH, Muller FM, Piscitelli SC, et al. Lipid formulations of amphotericin B: clinical perspectives for the management of invasive fungal infections in children with cancer. *Klin Padiatr*. 1998;210:264-273.

Safety and antifungal efficacy. Safety and antifungal efficacy of ABCD, ABLC, and L-AmB were demonstrated in an array of phase II and III clinical trials in immunocompromised, mostly adult patients with a wide spectrum of underlying disorders.^{131,283,371,549,557,688,716,725} The overall response rates in these trials ranged from 53% to 84% in patients with invasive candidiasis and 34% to 59%, respectively, in patients with presumed or documented invasive aspergillosis.^{249,290} A few randomized controlled trials were completed in which one of the newer formulations was compared with D-AmB. These studies consistently showed at least equivalent therapeutic efficacy and reduced nephrotoxicity of the investigated lipid formulation. Infusion-related side effects of fever, chills, and rigor were less frequent with L-AmB only.^{19,83,684,715,714} Substernal chest discomfort, respiratory distress, and sharp flank pain may occur during infusion of L-AmB^{322,552}; in comparative studies, hypoxic episodes associated with fever and chills occurred more frequently in ABCD recipients than in recipients of D-AmB.^{85,715} Mild increases in serum bilirubin and alkaline phosphatase have been observed with all three formulations, as well as mild increases in serum transaminases with L-AmB. Nevertheless, no case of fatal liver disease has occurred.^{249,290,729} An increased rate of hyperphosphatemia has been reported for L-AmB³⁴³; however, true hyperphosphatemia has to be carefully differentiated from pseudohyperphosphatemia that is due to interferences of L-AmB with assay systems for determination of serum phosphorus.^{318,446}

Experience in pediatric patients. Considerable numbers of pediatric patients have been treated with ABCD, ABLC, or L-AmB on protocols in the clinical trials cited earlier.⁶¹⁷ Separately published pediatric data are discussed in the following subsections.

ABCD. ABCD is a complex of amphotericin B and sodium cholesteryl sulfate in an approximate 1:1 molar ratio that forms disklike colloidal structures on dissolution.²⁴⁹ Estimated pharmacokinetic parameters in children are not significantly different from those in adult patients under conditions of steady state: mean AUC from 0 to 24 hours (AUC₀₋₂₄) is 7.10 mg/L/h (normalized to a 1-mg/kg per day dose); mean volume of distribution (V_d) is 4.57 L/kg, and mean total clearance (Cl) is 0.144 L/h/kg.¹³

A double-blind, randomized trial comparing ABCD (4 mg/kg per day) with D-AmB (0.8 mg/kg per day) for empirical antifungal therapy of febrile neutropenic patients that also included a larger number of pediatric patients found that ABCD was as effective but significantly less nephrotoxic than D-AmB.⁷¹⁵ Among children (0–15 years; mean, 8.8 years) with presumed or proved invasive fungal infections refractory to or intolerant of amphotericin B who were treated on five different open-label studies of ABCD with dosages that ranged from 0.8 to 7.5 mg/kg (mean, 4.5 mg/kg), 67% of patients reported infusion-related reactions, but nephrotoxicity, defined as an increase in serum creatinine to 2 times or more of the baseline value, was reported in only 12%.⁵⁷⁰

The published experience in the neonatal setting is limited to 16 infants with very low birth weight (779 ± 170 g; 25 ± 2 weeks) with invasive candidiasis and a serum creatinine concentration of 1.2 mg/dL or greater.³⁹³ Infants received 3 mg/kg ABCD on day 1, followed by 5 mg/kg per day thereafter; a second agent was permitted for candidemia that persisted for 7 or more days. Of 14 evaluable patients, 13 cleared the organism after therapy with ABCD alone (*n* = 8) or in combination with another agent (*n* = 5), and overall survival was 75%.

These data overall indicate no fundamental differences in disposition, safety, and antifungal efficacy of ABCD in contrast to adult populations. The US Food and Drug Administration (FDA)-approved indication has been treatment of probable or proven invasive aspergillosis refractory to or intolerant of D-AmB, and the approved dosage was 3 to 4 mg/kg per day, administered over the course of 2 hours. Marketing of ABCD has been discontinued in the United States and most of Europe due to a higher rate of infusion-related reactions relative to D-AmB in controlled clinical trials^{85,716} and the existence of better tolerated alternatives.

ABLC. ABLC is composed of dimyristoyl phosphatidylcholine/dimyristoyl phosphatidylglycerol (DMPC/DMPG) in a 1:1 molar ratio of lipid to amphotericin B and forms large, ribbon-like structures. The pharmacokinetic properties of ABLC were studied in whole blood in three pediatric patients with cancer who received the compound at 2.5 mg/kg over the course of 6 weeks for hepatosplenic candidiasis.⁶⁹⁸ Steady state was achieved by day 7 of therapy; after the final dose, the mean AUC₀₋₂₄ was 11.9 ± 2.6 mg/L/h, the mean C_{max} was 1.69 ± 0.75 mg/L, and clearance was 0.218 L/kg/h. In the six patients evaluable for safety assessment, mean serum creatinine levels were stable at the end of therapy and at 1-month follow-up and no increase in hepatic transaminases occurred. Five of the patients had infusion-related reactions to the first dose, which were prospectively monitored without prior premedication; however, infusion-related adverse reactions were well controlled thereafter by conventional premedications. All evaluable patients responded to therapy.

Safety and antifungal efficacy of ABLC were studied in 111 treatment episodes in pediatric patients (21 days to 16 years of age) refractory to or intolerant of conventional antifungal agents through an open-label, emergency-use protocol in the United States.⁶⁹⁶ ABLC was administered at a mean daily dosage of 4.85 mg/kg (range, 1.1–9.5 mg/kg per day) for a mean duration of 38.9 days (range, 1–198 days). The mean serum creatinine for the entire study population did not significantly change between baseline (1.23 ± 0.11 mg/dL) and cessation of ABLC therapy (1.32 ± 0.12 mg/dL) over 6 weeks. No significant differences were observed between baseline and end-of-therapy levels of serum potassium, magnesium, hepatic transaminases, alkaline phosphatase, and hemoglobin. Among 54 cases fulfilling criteria for evaluation of antifungal efficacy, a complete or partial therapeutic response was obtained in 38 patients (70%).

The safety and efficacy of ABLC also were assessed in 548 children and adolescents who were enrolled in the Collaborative Exchange of Antifungal Research registry. Most patients were either intolerant of or refractory to conventional antifungal therapy. Response data were evaluable for 255 of the 285 patients with documented single or multiple pathogens. A complete (cured) or partial (improved) response was achieved in 54.9% of patients. No significant difference was noted between the rates of new hemodialysis versus baseline hemodialysis. Elevations in serum creatinine of greater than 1.5 times baseline and greater than 2.5 times baseline values were seen in 24.8% and 8.8% of all patients, respectively. The overall response rate and safety profile in pediatric patients were consistent with earlier reported findings of smaller trials.⁷¹⁹

Eleven infants age 6 months and younger with candidemia were enrolled in the US open-label, emergency-use protocol.⁶⁹⁶ Of the 11 patients, 7 maintained a stable mean serum creatinine; in 4 patients, a rise in serum creatinine was observed, but in each case, the increase was less than 40% of the baseline value. No differences were observed between baseline and end-of-therapy mean bilirubin levels. Among the 8 evaluable infants, a complete response was observed in 6 (75%). A population pharmacokinetic study in 28 mostly premature neonates with invasive *Candida* infections demonstrated that the disposition of ABLC in neonates is similar to that observed in other age groups; weight was the only factor that influenced clearance.⁷³¹ The safety of ABLC in neonates is further supported by a retrospective case-control study in 35 infants with very low birth weight who received the compound for at least 2 weeks; treatment with ABLC was well tolerated and did not increase serum creatinine or decrease potassium.⁴¹

The current data suggest no fundamental differences in disposition, safety, and antifungal efficacy of ABLC in contrast to adults. The FDA-approved indication is treatment of invasive fungal infections refractory to or intolerant of D-AmB, and the approved dosage is 5 mg/kg per day administered over the course of 2 hours.

L-AmB. L-AmB (AmBisome) consists of small, unilamellar spherical vesicles (true liposomes) composed of hydrogenated soy phosphatidylcholine and distearoyl phosphatidylglycerol stabilized by cholesterol and combined with amphotericin B in a 2:0.8:1:0.4 molar ratio.²⁴⁹ Of note, a number of generic liposomal formulations of amphotericin B of various compositions exist in low- and middle-income countries.⁷ However, these agents are pharmacologically not interchangeable with L-AmB in the form of AmBisome. The pharmacokinetic properties of L-AmB in pediatric patients beyond the neonatal period were investigated in a formal phase II, dose-escalation trial investigating dosages of 2.5, 5, and 7.5 mg/kg in immunocompromised patients, as well as by using a population-based approach. The results of these studies indicate that the disposition of L-AmB in pediatric patients is not substantially different from that in adults and that weight is a covariate that determines clearance and volume of distribution.^{294,590} A pharmacokinetic pilot study was conducted in 12 children at risk for developing invasive fungal infections who received once-weekly, high-dose L-AmB (10 mg/kg over 2 hours) as prophylaxis. L-AmB was well tolerated and showed measurable amphotericin B plasma concentrations 7 days after the dose.⁴³³ Similarly, among a cohort of 46 high-risk patients who received L-AmB as prophylaxis at a dosage of 2.5 mg/kg twice weekly, measurable plasma concentrations were observed at the end of the dosing interval.⁷⁷ These findings suggest that once weekly^{272,433} as well as twice weekly⁷⁷ administration may provide useful protection against fungal infections.

Many pediatric patients have been enrolled in clinical trials with L-AmB but have not been reported separately.^{438,684} Two hundred four children (mean age, 7 years) with neutropenia and fever of unknown origin were randomized in an open-label, multicenter trial to receive conventional D-AmB at 1 mg/kg per day ($n = 63$), L-AmB at 1 mg/kg per day ($n = 70$), or L-AmB at 3 mg/kg per day ($n = 71$) for empirical antifungal therapy.³³¹ Twenty-nine percent of patients treated with L-AmB 1, 39% of patients treated with L-AmB 3, and 54% of patients treated with D-AmB experienced adverse effects ($P = .01$); nephrotoxicity, defined as 100% or more increase in serum creatinine from baseline, was noted in 8%, 11%, and 21%, respectively (not significant [NS]). Hypokalemia (<2.5 mmol/L) occurred in 10%, 11%, and 26% of patients, respectively ($P = .02$); increases in serum transaminase levels (≥ 110 U/L) occurred

in 17%, 23%, and 17%, respectively (NS); and increases in serum bilirubin (≥ 35 μ mol/L) occurred in 11%, 12%, and 10% of patients, respectively. L-AmB at either 1 or 3 mg/kg per day was significantly safer and at least equivalent to D-AmB with regard to resolution of fever of unknown origin. L-AmB was well tolerated and effective in cohorts of immunocompromised children requiring antifungal therapy for proved or suspected infections, including patients with bone marrow transplants for primary immunodeficiencies⁵⁰³ patients with cancer^{100,550} and critically ill patients.⁵⁹⁹ A phase IV analysis of 141 courses of L-AmB administered for a mean of 17 days' duration at a mean maximum dosage of 2.5 mg/kg for various indications to pediatric patients with cancer and hematopoietic stem cell transplantation (HSCT) revealed a low rate of adverse events (4%), necessitating discontinuation. Whereas mean aspartate transaminase, alanine transaminase, alkaline phosphatase, and bilirubin values were slightly higher at the end of treatment ($P = .01$), bilirubin and creatinine values were not different from baseline.³⁴⁸

L-AmB 2.5 to 7 mg/kg per day was evaluated prospectively in 24 infants with very low birth weight (mean birth weight, 847 ± 244 g; mean gestational age, 26 weeks) with systemic candidiasis. The mean duration of therapy was 21 days; the cumulative L-AmB dose was 94 mg/kg. Fungal eradication was achieved in 92% of the episodes; 20 (83%) infants were considered clinically cured at the end of treatment. No major adverse effects were recorded. One infant developed increased bilirubin and hepatic transaminase levels during therapy. Four (17%) infants died; in 2 of them (8%), the cause of death was attributed directly to systemic candidiasis.³²⁶ In a second study undertaken by the same investigators, high-dose (5–7 mg/kg per day) L-AmB was evaluated prospectively in 41 episodes of systemic candidiasis occurring in 37 neonates (36 of 37 were premature infants with very low birth weights). Twenty-eight, five, and eight infants received 7, 6 to 6.5, and 5 mg/kg per day, respectively. Median duration of therapy was 18 days; median cumulative dose was 94 mg/kg. Fungal eradication was achieved in 39 of 41 (95%) episodes. Fungal eradication was achieved more rapidly in patients treated early with high doses and in patients who received high-dose L-AmB as first-line therapy.³²⁵ Further prospective³⁷ and retrospective⁴¹⁶ cohort studies attest to the safety of L-AmB in infants with very low birth weight. Of note, the higher mortality reported in a single center analysis for infants with invasive candidiasis treated with lipid formulations relative to conventional D-AmB or fluconazole⁴⁹ is likely due to differences in acuity of illnesses and comorbidities rather than pharmacokinetic considerations.

Current data indicate no substantial differences in pharmacokinetics and pharmacodynamics of L-AmB between pediatric and adult patients. The FDA-approved dosages are 3 mg/kg per day (empirical antifungal therapy in febrile neutropenic patients), 3 to 5 mg/kg per day (therapy of invasive infections intolerant or refractory to D-AmB), 6 mg/kg per day for cryptococcal meningitis, and 3 mg/kg on days 1 through 5, 14, and 21 for immunocompetent and 4 mg/kg on days 1 through 5, 10, 17, 24, 31, and 38 for immunocompromised patients with visceral leishmaniasis, administered over the course of 2 hours. In Europe, L-AmB is approved for first-line treatment of invasive mycoses, empirical antifungal therapy, and treatment of leishmaniasis.

Indications. The lipid formulations of AmB have been a major advance in the management of invasive opportunistic fungal infections in immunocompromised patients. All three compounds have less renal toxicity than conventional amphotericin B, as defined by development of azotemia; distal tubular toxicity also may be somewhat reduced. Infusion-related reactions of fever, chills, and rigor occur substantially less frequently only with L-AmB, and no new toxicities have been noted. The available pharmacokinetic and safety data from children so far indicate no fundamental differences from data obtained in the adult population.

Therapeutically, the lipid formulations are at least as effective as is conventional amphotericin B deoxycholate for treatment of most opportunistic human mycoses, and these formulations can be effective if conventional amphotericin B has failed. The specific clinical indications of the lipid formulations are discussed in the respective fungal disease chapters and are summarized in [Tables 240.2 to 240.4](#).

Flucytosine

Flucytosine (5-fluorocytosine [5-FC]; Ancobon; Ancotil; and generic) is a low-molecular-weight, water-soluble, synthetic fluorinated pyrimidine

analogue (Fig. 240.3). It is taken up into the fungal cell by the fungus-specific enzyme cytosine permease and is converted in the cytoplasm by cytosine deaminase to 5-fluorouracil, a potent antimetabolite that causes RNA miscoding and inhibits DNA synthesis at the level of thymidylate synthase (Fig. 240.4).¹⁷⁰ Flucytosine is relatively nontoxic to mammalian cells because of the absence or very low level of activity of cytosine deaminase. In the United States, flucytosine is available only as an oral formulation; an intravenous formulation is available outside the United States in select countries.

Antifungal activity. The antifungal activity of flucytosine in vitro is essentially limited to *Candida* spp., *C. neoformans*, *Cryptococcus gattii*, *Saccharomyces cerevisiae*, *Rhodotorula* spp., and some dematiaceous molds.^{159,205,219,292,518,520,642} Flucytosine generally is thought to have no or weak activity against *Aspergillus* spp. and other hyaline molds,^{217,419} although this lack of activity in vitro may be pH dependent⁶²⁶ and does not correlate with the documented efficacy in animal models.⁶²⁸ Notably, whereas *Candida krusei* appears to be less susceptible to flucytosine, the compound is highly active against *C. glabrata*.^{170,205,518} Synergistic or additive effects in combination with amphotericin B have been observed against *Candida*^{431,450} and *Aspergillus* spp.⁶²⁷ and in combination with amphotericin B, fluconazole, voriconazole, and posaconazole against *C. neoformans*.^{47,271,432,477,586} Combination with echinocandins was additive or indifferent in vitro against *Candida* spp.³²⁸

Two mechanisms of resistance have been reported: (1) mutations in enzymes necessary for cellular uptake and transport of flucytosine or its metabolism and (2) increased synthesis of pyrimidine that competes with the fluorinated antimetabolites of the compound.^{162,671} In pretreatment isolates, intrinsically resistant strains have been found in 3% to 8% of *C. albicans*, in 0% to 8% of non-*albicans Candida* spp., and in 2% or fewer of *C. neoformans* isolates.^{432,518} In an analysis of 8803 clinical isolates comprising 18 *Candida* spp. obtained from more than 200 medical centers worldwide, primary resistance to flucytosine was an uncommon occurrence among *Candida* spp. (95% sensitive, 2% intermediate, and 3% resistant), with the exception of *C. krusei* (5% sensitive, 67% intermediate, and 28% resistant).⁵¹⁸ Development of resistance to flucytosine can be observed during treatment,²⁰⁵ and it is thought to be caused predominantly by selection of resistant clones.⁶⁷¹

FIG. 240.3 Structural formulas of cytosine, flucytosine, and fluorouracil.

FIG. 240.4 Schematic of intracellular pathways and mechanism of action of flucytosine. 5-FC, Flucytosine; FdUMP, 5-fluorodeoxyuridine monophosphate; 5-FU, 5-fluorouracil; FUDP, 5-fluoridine diphosphate; FUMP, 5-fluoridine monophosphate; FUTP, 5-fluoridine triphosphate. (Modified from Groll AH, Piscitelli SC, Walsh TJ. Antifungal pharmacodynamics: concentration-effect relationships in vitro and in vivo. *Pharmacotherapy*. 2001;21[suppl. 8]:133-148; and Vermes A, Guchelaar HJ, Dankert J. Flucytosine: a review of its pharmacology, clinical indications, pharmacokinetics, toxicity and drug interactions. *J Antimicrob Chemother*. 2000;46:171-179.)

As a consequence, flucytosine is rarely given alone but instead is given in combination with amphotericin B or fluconazole.

Pharmacodynamics. Time-kill assays against *Candida* spp. and *C. neoformans* demonstrated a predominantly concentration-independent fungistatic (99% reduction in colony-forming units) activity of flucytosine at concentrations exceeding the MIC of the investigated isolates.^{389,655}

A prolonged PAFE against these organisms was noted consistently that was dependent on concentration and duration of exposure and ranged from 0.8 to 10 hours.^{441,577,578,740} Investigation of pharmacokinetic and pharmacodynamic relationships in a neutropenic mouse model of disseminated candidiasis that used the residual fungal burden in kidney tissue as the endpoint of antifungal efficacy revealed that both the time above the MIC and the AUC/MIC ratio were important in predicting efficacy; maximal efficacy was observed when levels exceeded the MIC for only 20% to 25% of the 24-hour dosing interval.²⁹ In experiments that used a pharmacodynamic model of disseminated candidiasis and bridging to humans by population pharmacokinetics and Monte Carlo simulation, an in vivo drug exposure breakpoint for flucytosine was apparent when serum levels were greater than the MIC for 45% of the dosing interval. The Monte Carlo simulations suggested that, using a human dose of 100 mg/kg per day in four divided doses, flucytosine resistance was defined at an MIC of 32 mg/L. Target attainment rates after administration of 25, 50, and 100 mg/kg per day were similar.³⁰¹ These data collectively suggest that lower dosages or less frequent dosing may yield identical antifungal efficacy while further reducing potential toxicities of flucytosine that are thought to be concentration dependent.²⁰⁵

Pharmacokinetics. Flucytosine is absorbed readily from the gastrointestinal tract, and oral bioavailability exceeds 80% (Table 240.6). C_{max} occurs 1 to 2 hours after administration. As a water-soluble compound, flucytosine has negligible protein binding (4%) and is widely distributed in the body, with a volume of distribution that approximates that of total body water. Mean CSF concentrations usually are 65% to 90% of simultaneous plasma concentrations. The drug penetrates well into peritoneal fluid, inflamed joints, and other fluid compartments, including the eye.^{72,141,251}

In humans, less than 1% of a given dose of flucytosine is thought to undergo hepatic metabolism.⁴¹⁰ Some evidence suggests that bacteria of the gastrointestinal flora deaminate flucytosine to resorbable 5-fluorouracil,^{274,411} a finding that may account for some of the toxicities observed after oral administration of the drug. Approximately 95% of a given dose of flucytosine is excreted into the urine in unchanged, active form by simple glomerular filtration.²⁵¹ Because the compound's elimination parallels the glomerular filtration rate, adjustment of the dosage is necessary in patients with impaired renal function.¹⁴⁴ In patients undergoing hemodialysis, a dose of 37.5 mg/kg is recommended after dialysis; in those undergoing hemofiltration, the dosage needs to be adjusted to the individual filtration rate.^{312,374} In peritoneal dialysis, the compound can be administered systemically or intraperitoneally.⁴⁴⁰

TABLE 240.6 Pharmacokinetics of Flucytosine in Adults

Parameter or Characteristic	Value
Oral bioavailability	≥80%
C _{max}	50–120 µg/mL ^a
T _{max}	1–2 h
Protein binding	4%
Vd _{ss}	0.6–0.7 L/kg
t _{1/2β}	3–6 h
Clearance	≥95% renal
Unchanged drug in urine	≥95%
Relative cerebrospinal fluid levels	65–90%

^aAt steady state in patients with cryptococcal meningitis receiving 4 × 2 g/day orally. Modified from Groll AH, Piscitelli SC, Walsh TJ. Antifungal pharmacodynamics: concentration-effect relationships in vitro and in vivo. *Pharmacotherapy*. 2001;21(suppl 8):133–148.

C_{max}, Peak plasma concentration; T_{max}, time until occurrence of peak plasma concentration; Vd_{ss}, volume of distribution at steady state.

Although the data are limited, impaired liver function does not appear to alter the disposition of flucytosine.¹⁴¹

In infants and children, the pharmacokinetic properties of flucytosine have not been systematically characterized. However, because of very similar physicochemical and pharmacokinetic properties, developmental changes in disposition similar to those found with fluconazole can be anticipated. Indeed, a similarly marked interindividual variability in clearance and volume of distribution has been reported in neonates⁴⁴ that renders uniform dosing recommendations in this population impossible.

A starting dosage for both adults and children of 100 mg/kg daily divided into three or four doses is recommended currently. Monitoring of plasma concentrations is essential to adjust dosage to changing renal function and avoid toxicity. After oral administration, near peak levels 2 hours after dosing overlap with trough levels as patients reach steady state, and thus these levels are sufficient for therapeutic monitoring.²⁰⁵ In practice, plasma levels between 40 (trough) and less than 100 mg/L (peak) correlate with antifungal efficacy and seldom are associated with hematologic adverse effects.^{205,672} However, retrospective evaluations in the United Kingdom revealed that only a fraction of plasma levels ordered for therapeutic monitoring were in this concentration range.^{504,613}

Adverse effects. Common adverse effects associated with flucytosine that occur in 5% to 6% of patients include gastrointestinal intolerance and reversible elevations of hepatic transaminases and alkaline phosphatase. Rarer side effects are skin rashes, blood eosinophilia, and crystalluria.²⁵¹ Hematologic adverse effects have been reported in overall 6% of patients receiving oral flucytosine and may include neutropenia, thrombocytopenia, or pancytopenia. Notably, hematologic adverse effects occur less frequently if plasma levels of flucytosine do not exceed 100 mg/L.^{205,251}

Drug interactions. Orally administered, nonresorbable antibiotics and administration of aluminum-based or magnesium hydroxide-based antacids may delay but do not impair absorption of the compound from the gastrointestinal tract.²⁵¹ 5-FC undergoes only minor hepatic metabolism, and it is not known to interfere with the cytochrome P (CYP)450 enzyme system. However, any drug that can cause a reduction in the glomerular filtration rate may lead to increased flucytosine serum levels and thereby has the potential to enhance 5-FC-associated toxicity. This phenomenon almost invariably is encountered with concomitant administration of amphotericin B, but it can occur similarly with numerous antimicrobial agents, anticancer drugs, and cyclosporine, to name only the most common examples.¹⁴¹ The anticancer drug cytosine arabinoside (Ara-C) competitively inhibits the action of 5-FC, and these drugs should not be given concomitantly.⁹⁹

Clinical indications. Because of the propensity of susceptible organisms to develop resistance in vitro,⁵²⁹ 5-FC traditionally is not administered as a single agent. Ample laboratory and clinical experience exists regarding

the combination of D-AmB and 5-FC (see Table 240.2).^{170,251,671} Randomized clinical trials established the use of D-AmB in combination with 5-FC as standard for induction therapy of cryptococcal meningitis in non-human immunodeficiency virus (HIV)-infected and HIV-infected patients.^{59,657} In a recent large randomized three-arm clinical trial in HIV-infected patients with cryptococcal meningitis, D-AmB 1 mg/kg per day plus 5-FC 100 mg/kg per day, as compared with D-AmB alone, was associated with improved survival.¹⁴² Treatment with D-AmB plus 5-FC in this¹⁴² and a previous small but well-designed trial⁸⁹ was associated with significantly increased rates of yeast clearance from cerebrospinal fluid, indicating that the combination of D-AmB and 5-FC is the most rapidly fungicidal regimen.⁸⁹ While controlled data for standard doses of ABLC are limited,²⁹⁵ L-AmB has been shown to be equally effective to D-AmB at doses of 3 and 6 mg/kg and day,²⁶⁹ and pharmacokinetic/pharmacodynamic bridging from a murine model of cryptococcal meningoencephalitis suggests near maximum efficacy with a dosage of 6 mg/kg per day of L-AmB or the combination of L-AmB 3 mg/kg per day plus 5-FC.⁴⁸³

Although no comparative trials have been performed, the cumulative clinical experience supports the combination of amphotericin B with 5-FC for the treatment of *Candida* infections involving deep tissues, particularly in critically ill patients and when non-*albicans Candida* spp. are involved.^{205,303,420,631} This includes *Candida* meningitis, endophthalmitis, endocarditis, vasculitis, and peritonitis, as well as osteoarticular, renal, and disseminated candidiasis.^{251,685}

The combination of 5-FC with fluconazole is an option for cryptococcal meningitis, when treatment with conventional or liposomal amphotericin B is not feasible.^{373,442,444,481} Options for situations when 5-FC is not available include monotherapy with amphotericin B or the combination of amphotericin B and fluconazole.^{142,400} The combination of 5-FC and fluconazole also may be useful as second-line therapy for individual patients with invasive *Candida* infections involving aqueous body compartments.

Antifungal Triazoles

The antifungal azoles are a class of synthetic compounds that have one or more azole rings and—attached to one of the nitrogen atoms—a more or less complex side chain. Whereas the imidazoles have two nitrogen atoms, the triazoles have three in the five-member ring. The triazole ring confers improved resistance to metabolic degradation, greater target specificity, and an expanded spectrum of activity.^{236,235} The imidazoles miconazole and ketoconazole were the first azole compounds developed for systemic treatment of human mycoses. Severe toxicities associated with the drug carrier (miconazole) and erratic absorption and significant interference with the human CYP450 system (ketoconazole), however, limited their clinical usefulness.²⁵¹ The triazoles fluconazole and itraconazole (Fig. 240.5), in contrast, have become extremely useful components of the antifungal armamentarium. Overall, they are well tolerated and possess a broad spectrum of activity. Whereas fluconazole and itraconazole have been available since the 1990s, a next generation of antifungal triazoles entered clinical practice a decade ago; these so-called second-generation triazoles include voriconazole, posaconazole, and isavuconazole (Fig. 240.6).²⁹³

Mechanism of action. The antifungal azoles, as a class, target ergosterol biosynthesis by inhibiting the fungal CYP450-dependent enzyme lanosterol 14- α -demethylase. This inhibition interrupts the conversion of lanosterol to ergosterol and thus leads to accumulation of aberrant 14- α -methylsterols and depletion of ergosterol in the fungal cell membrane (Fig. 240.7). These effects alter cell membrane properties and function and, depending on organism and compound, may lead to cell death or inhibition of cell growth and replication. In addition, the azoles also inhibit CYP450-dependent enzymes of the fungal respiration chain, but the contribution of this action to their overall activity is unclear. Interaction with structurally similar mammalian CYP450-dependent enzyme systems is responsible for most toxicities and drug interactions of this class of compounds.^{251,663}

Antifungal activity. Fluconazole and itraconazole are active principally against dermatophytes, *Candida* spp., *C. neoformans*, *C. gattii*, *T. asahii*, and other uncommon yeast organisms, as well as against dimorphic fungi such as *Histoplasma capsulatum*, *Coccidioides* spp., *Blastomyces*

dermatitidis, *Paracoccidioides brasiliensis*, and *Sporothrix schenckii*.^{236,235,642} These drugs have less activity against *C. glabrata* and none against *C. krusei*.^{251,546} Clinically useful activity against *Aspergillus* spp. and dematiaceous molds is restricted to itraconazole, and both itraconazole and fluconazole are considered inactive against *Fusarium* spp. and the Mucorales.²⁵¹ The second-generation triazoles voriconazole, posaconazole, and isavuconazole have enhanced target activity and are active against a wide spectrum of clinically important fungi, including *Candida* spp., *T. asahii*, *C. neoformans*, *Aspergillus* spp., *Fusarium* spp., and other hyaline molds, as well as dematiaceous and dimorphic molds.^{8,111,116,119,251,293} In contrast to fluconazole and itraconazole, all are active against *C. glabrata* and *C. krusei*; posaconazole and isavuconazole also are active against Mucorales, a feature that distinguishes it from all other azole compounds.²⁶⁰

Resistance. Several mechanisms of azole resistance in *Candida* spp. have been identified and include, but are not limited to, molecular

alterations at the target binding site, increased target expression, and induction of cellular efflux pumps.^{49,521,571,714} In contrast to pathogenic bacteria, genetic exchange mechanisms are largely unknown in fungi. Exposure-induced cumulative molecular events that lead to stable azole resistance have been reported; however, in the clinical setting, resistance is encountered most commonly in the form of a primarily resistant species or through selection of resistant subclones during exposure to azoles.^{546,714}

Acquisition of microbiologic and clinical azole resistance was reported first in patients with chronic mucocutaneous candidiasis who were receiving long-term therapy with ketoconazole.³⁰⁴ In the 1990s, before the advent of highly active antiretroviral therapy, azole-resistant oropharyngeal and esophageal candidiasis became a major clinical conundrum in patients with advanced HIV infection.^{540,556} Emergence of *C. glabrata* and *C. krusei* infections in association with fluconazole prophylaxis has been observed in several bone marrow transplant

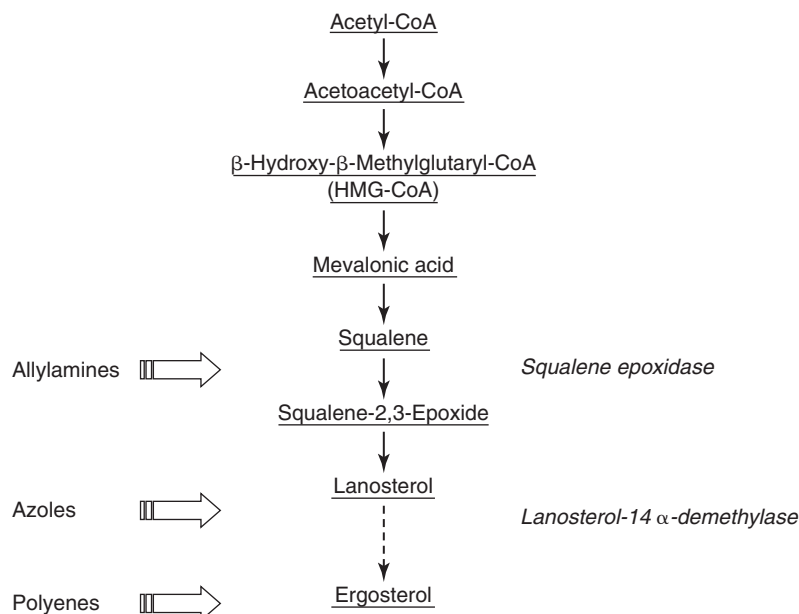

FIG. 240.7 Ergosterol biosynthesis and targets of current antifungal agents. CoA, Coenzyme A. (Modified from Groll AH, Walsh TJ. Uncommon opportunistic fungi: new nosocomial threats. *Clin Microbiol Infect* 2001;7[suppl 2]:8-24.)

centers^{316,427,724,723} and in large cancer centers.³⁵⁰ However, a large prospective series from Seattle showed an altogether low incidence of breakthrough candidemia (4.6%); in two-thirds caused by *C. glabrata* or *C. krusei* and a low attributable mortality (20%) in patients receiving fluconazole prophylaxis despite frequent colonization with fluconazole-resistant *Candida* spp.⁴²⁷ More recently, emergence of azole-resistant *C. parapsilosis* bloodstream infections has been reported in a laboratory based sentinel surveillance in South Africa: Of 531 *C. parapsilosis* isolates, only 199 (37%) were susceptible to fluconazole and voriconazole, limiting the choice of antifungal agents for management of candidemia in a resource-limited region.²³⁴ Although cross-resistance of *Candida* spp. to antifungal azoles is a common occurrence,^{50,229,463,507} it is not obligate; for example, patients with microbiologic and clinical fluconazole-resistant mucosal candidiasis may respond to itraconazole or second-generation triazoles.^{280,563} Nonetheless, patients who have been exposed to azoles and who have breakthrough candidemia or an azole-resistant *Candida* isolate have a high likelihood of cross-resistance, and treatment with alternative agents is advised.^{234,409,495} Acquired resistance to azoles has been documented in patients with *C. neoformans* meningitis,^{70,604,605} and increasingly, reports are being published of secondary azole resistance and azole cross-resistance in filamentous fungi, especially *Aspergillus* spp.^{110,152,454,521,609,618,659,660,673}

Fluconazole

Fluconazole (Diflucan; generic forms) is a synthetic, low-molecular-weight, water-soluble bis-triazole (see Fig. 240.5). Relative to ketoconazole, the compound has similar potency but is much more specific and therefore better tolerated. Fluconazole is active against *Candida* spp., *C. neoformans*, *C. gattii*, *T. asahii*, and endemic dimorphic fungi, but not against *Aspergillus* spp. and other hyaline or dematiaceous molds. Fluconazole has intermediate activity against *C. glabrata* and is inactive against *C. krusei*.^{227,236,519,642}

Pharmacodynamics. Fluconazole generally is considered to be a fungistatic agent.²⁵² Time-kill assays performed over incubation periods of 24 to 48 hours in susceptible *Candida* spp. and *C. neoformans* showed fungistatic activity of fluconazole with variable concentration-related growth effects.^{94,93,157,341,342} However, time-kill studies that used extended periods of incubation up to 14 days and nonproliferating growth conditions demonstrated direct fungicidal activity of fluconazole against *C. albicans*.⁶¹² These observations raise the possibility that fluconazole may ultimately be able to eliminate *Candida* spp. without help from host defenses. Whether fungicidal activity in vitro portends a therapeutic advantage, however, continues to be a matter of debate.⁶⁷⁰ In serum-free growth media, fluconazole displays no measurable PAFE against *C.*

albicans and *C. neoformans*, but concentration-dependent PAFEs of 1 to 3.6 hours were observed in the presence of fresh serum. Finally, pretreatment of *C. albicans* with fluconazole increased its vulnerability to killing by polymorphonuclear leukocytes.^{188,444}

In vivo pharmacodynamic studies of fluconazole in murine models of disseminated *C. albicans* candidiasis using the fungal burden in kidney tissue as an endpoint for antifungal efficacy collectively suggested that the AUC/MIC ratio is the pharmacodynamic parameter that best predicts antifungal efficacy of fluconazole^{28,399,614} and that dosing regimens that produce prolonged sub-MIC concentrations are associated with development of resistance.²⁴ The linear pharmacokinetics and the available experimental and clinical data are in support of once-daily dosing regimens. Pharmacodynamic models and several animal studies demonstrate a correlation between the MIC of fluconazole and antifungal efficacy.^{17,46,494,545,553,686} A postmarketing analysis of 1295 patient-episode-isolate events from 12 published clinical studies demonstrates success rates of 85% for those episodes in which the fluconazole MIC was 8 mg/L or less, 67% for those episodes in which the MIC was 16 to 32 mg/L, and 42% for those episodes with isolates that had an MIC of 64 mg/L or higher.⁵¹⁷ Of note, the additional consideration of wild-type MIC distributions and epidemiologic cutoff values has led to the proposition of species-specific clinical breakpoints that may be more sensitive to detect emerging resistance to common *Candida* species.⁵¹⁴ The pharmacokinetics and pharmacodynamics of antifungal agents in treating resistance fungi in children has been recently reviewed in detail elsewhere.⁶¹⁹

Pharmacokinetics. Fluconazole is formulated for oral and parenteral use, and its disposition is independent of route and formulation. Fluconazole exhibits linear plasma pharmacokinetics that fit best into a two-compartment open model.⁸⁸

Independent of food or intragastric pH, the oral bioavailability of fluconazole is greater than 90%. C_{max} occurs 1 to 2 hours after ingestion. Multiple dosing increases C_{max} approximately 2.5-fold. Steady state generally is reached within 4 to 7 days after once-daily dosing, but it can be achieved rapidly by doubling the dose on the first day.^{227,236} Because of the free solubility in water, protein binding is low. Fluconazole distributes well into virtually all tissue sites and body fluids. The ratio of CSF and serum concentrations ranges from 0.5 to 0.9 during the dosing interval, and penetration into brain tissue and the different compartments of the eye is excellent. Fluconazole is relatively stable to metabolic conversion; more than 90% of a dose is excreted by the kidney, with approximately 80% recovered as unchanged, active drug and 11% recovered as inactive metabolites.^{88,227,236} Because excretion of fluconazole parallels the glomerular filtration rate, the dosage must be

adjusted in patients with renal impairment. A 50% reduction is required in patients with a creatinine clearance of 50 mL/min or less, and a 75% reduction is required in patients with a creatinine clearance of less than 21 mL/min; the initial loading dose need not be adjusted.^{65,236} Fluconazole is dialyzable; in patients undergoing hemodialysis, 100% of the target dose is given after each dialysis session. In continuous venovenous hemofiltration and hemodiafiltration, dosing at the higher end of the dosing range (i.e., 800 mg/day in adults) is suggested.^{64,584} A dose of 150 mg in a single 2-L dialysate bag has been used for continuous ambulatory peritoneal dialysis.^{212,227,464,478,580,639} Hepatic insufficiency per se does not require adjustments of dosing, but careful monitoring of additional hepatic toxicity is required.⁵⁵⁸ Finally, infants and children requiring extracorporeal membrane oxygenation (ECMO) were shown to have a higher volume of distribution but similar clearance relative to controls not on ECMO and may require higher loading doses for treatment.^{704,705}

The plasma pharmacokinetic properties of fluconazole in pediatric age groups reflect developmental changes in the volume of distribution and clearance that are characteristic for a highly water-soluble drug with minor metabolism and predominantly renal elimination (Table 240.7). Except for premature neonates, in whom clearance initially is decreased, pediatric patients tend to have an increased weight-normalized clearance rate from plasma that leads to a shorter half-life in contrast to that in adults.^{87,366,380,465,576,589,635} Whereas population-based pharmacokinetic studies do not exist for children, gestational age at birth, postnatal age, and creatinine level were identified as parameters of impact on clearance of fluconazole in premature infants.^{679,680} Because exposure over the course of time appears to be the most predictive pharmacodynamic parameter,^{28,399} fractionating the dose is not required in infants and children, despite the shorter half-life in these age groups. From a practical standpoint, a dosage of 12 mg/kg per day in children approximates the plasma exposure achieved in adults receiving the licensed therapeutic dose of 400 mg/day.³⁸⁰ This pediatric dosage, which does not include neonates, also is consistent with that recommended in the FDA package labeling.

Adverse effects. In adults, fluconazole has been administered safely over prolonged periods at dosages of up to 1200 mg/day; dose-escalation to 1600 mg/day resulted mainly in increased hepatotoxicity, and dose-limiting neurotoxicity was observed at 2000 mg/day.¹⁸ Compiled data from adult patients who received the drug at dosages of 100 to 400 mg/day over the course of at least 7 days indicate an overall incidence of at least possibly related adverse effects of 16%; significant adverse effects or laboratory abnormalities leading to the discontinuation of the drug were noted in overall 2.8%.²³⁶ Nausea, vomiting, and other gastrointestinal symptoms are seen in fewer than 5% and skin rashes and headaches in fewer than 2% and are usually reversible; asymptomatic hepatic transaminase elevations were reported in as many as 7% of adult patients.^{125,236}

In pediatric patients of all age groups, at dosages up to 12 mg/kg per day, fluconazole generally is well tolerated. The most common reported side effects in pediatric patients include gastrointestinal

disturbances (8%), increases in hepatic transaminases (5%), and skin reactions (1%); toxicity-related discontinuation of therapy with fluconazole occurs in approximately 3% of patients.⁴⁸⁰ In a systematic review of the compound's safety in pediatric patients including 90 articles and 4209 patients, the rate of toxicity induced discontinuations was 1%; hepatic toxicity and gastrointestinal disturbances were the most frequent adverse effects.¹⁸¹ Severe side effects, including severe hepatotoxicity and exfoliative skin reactions, have been rarely reported in association with fluconazole therapy.^{125,245}

Drug interactions. Fluconazole undergoes minimal CYP450-mediated metabolism; it inhibits CYP2C9, CYP3A4 and CYP2C19 in vitro and interacts with enzymes involved in glucuronidation, thus leading to certain significant drug-drug interactions.^{125,240,261,526} Most important, concurrent therapy with cisapride, pimozide, quinidine, erythromycin, and newer antihistamines results in inhibition of the metabolic pathways of these drugs and potentially serious ventricular arrhythmias associated with QTc prolongation and is therefore strictly contraindicated.²⁵¹ By similar mechanisms, fluconazole can precipitate phenytoin toxicity,⁴⁴⁵ may lead to increased plasma concentrations of cyclosporine, tacrolimus, and sirolimus,^{377,491} and may potentiate the effects of short-acting benzodiazepines, carbamazepine, warfarin, sulfonylurea drugs, rifabutin, and nifedipine.^{349,377,486,568} Fluconazole also may interfere with the plasma clearance of cyclophosphamide, a widely used anticancer agent that must be metabolized by CYP450 enzymes to produce alkylating species. This interaction may potentially result in a relevant reduction in the therapeutic efficacy of cyclophosphamide.⁷³⁵ Further potential interactions with anticancer drugs have been observed with vincristine,⁶³⁰ busulfan,⁹² and all-*trans*-retinoic acid.⁵⁸⁷ This adverse interaction with vincristine is a serious concern in pediatric oncology that includes all of the currently licensed triazoles.⁴⁵⁶ The interaction may result in vasomotor collapse, seizures, and paralytic ileus. As vincristine is widely used in pediatric lymphoid malignancies, awareness of this potentially serious interaction with systemic antifungal triazoles is important.

Clinical indications. The clinical indications for fluconazole are summarized in Tables 240.2, 240.4, 240.8, and 240.9. Fluconazole is highly effective against superficial infections caused by dermatophytes and *Pityrosporum* spp.,^{115,210,267} and it has excellent activity in the treatment of mucosal candidiasis, including vaginal, oropharyngeal, esophageal, and chronic mucocutaneous candidiasis.^{201,250,287,418}

Several controlled studies including both neutropenic and non-neutropenic adult patients indicated that intravenous fluconazole 400

Antifungal agents. In: Mandell GL, Bennett JE, Dolin R, editors. *Principles and Practice of Infectious Diseases*. 4th ed. New York: Churchill Livingstone; 1995:401–410; and Walsh TJ, Gonzalez C, Lyman CA, et al. Invasive fungal infections in children: recent advances in diagnosis and treatment. *Adv Pediatr Infect Dis*. 1996;11:187–290.

to 800 mg/day is as effective as D-AmB 0.5 to 1 mg/kg per day against candidemia and other forms of invasive candidiasis, but it is better tolerated.^{15,20,498,522,544,546} Fluconazole thus can be used for invasive *Candida* infections caused by susceptible organisms in patients who are in stable condition.^{498,546,670} In patients who have received antifungal azoles for prophylaxis, however, breakthrough infections are likely to be caused by fluconazole-resistant *Candida* spp.,^{366,427} and alternative agents are recommended. The recommended pediatric dosage range of fluconazole beyond the neonatal period is 6 to 12 mg/kg per day; in view of the faster clearance rate and the absence of population pharmacokinetics, however, 12 mg/kg per day may be the most appropriate dosage.^{117,123,257,656} Although controlled data are lacking in this special population,¹²² fluconazole is a useful agent for treatment of invasive *Candida* infections in the neonatal setting. In six published series including 10 or more patients with proved invasive *Candida* infections, treatment with fluconazole at a daily dosage of usually 5 to 6 mg/kg was successful in 83% to 97%, and crude mortality ranged from 10% to 33%. In none of the 125 patients was fluconazole discontinued because of toxicity.^{71,82,171,172,198,311,681} For infants, population-based pharmacokinetics and Monte Carlo simulation showed that for the treatment of invasive candidiasis, a dose of at least 12 mg/kg per day in the first 90 days after birth is needed to achieve an AUC/MIC index greater than 50 for *Candida* spp. with MIC less than 8 μg/mL in 90% or more of infants at less than

30 weeks' gestation and 80% of infants at 30 to 40 weeks' gestation, respectively; according to the model, infants with serum creatinine of 1.3 mg/dL or greater have a slower clearance rate, and dose adjustment is indicated if creatinine does not improve within 96 hours.^{679,680} A loading dose of 25 mg/kg has been advocated for rapid attainment of target therapeutic drug concentrations.⁵²⁵

Fluconazole has been useful in the treatment of focal *Candida* urinary tract infections and uncomplicated funguria, and it has been used successfully in *Candida* peritonitis, endocarditis, osteomyelitis, meningitis, and endophthalmitis.^{251,384} Further potential indications for fluconazole beyond the treatment of acute invasive *Candida* infections include consolidation therapy for chronic disseminated candidiasis^{14,330} and cryptococcal meningitis.^{562,657} High-dose fluconazole is an option for systemic infections caused by the yeast *T. asahii*.^{16,259} Fluconazole is the current drug of choice for treatment of coccidioidal meningitis,^{214,569} and it has proven effectiveness in nonmeningeal coccidioidal infections.^{102,245} Fluconazole appears comparatively less active than itraconazole in the treatment of paracoccidioidomycosis, blastomycosis, histoplasmosis, and sporotrichosis.^{158,213,270,331,332,496,497,712}

Fluconazole can prevent mucosal candidiasis in patients with HIV infection or cancer,^{244,479,530} and it has proved efficacy in preventing invasive *Candida* infections in high-risk patients with acute leukemia or with bone marrow or liver transplants.^{232,554,727} Fluconazole, given at 400 mg once daily to adults from the start of the conditioning regimen until day 75, can reduce the frequency of invasive *Candida* infections and lower mortality at day 110 after allogeneic bone marrow transplantation,⁶⁰⁷ and it also may provide persistent protection against invasive candidiasis and *Candida*-related death. Fluconazole can decrease the frequency of severe, gut-related graft-versus-host disease (GVHD), and it has an independent overall survival benefit of 17% at 8 years after the end of treatment.⁴²⁶ Fluconazole also has been shown to reduce the incidence of *Candida* infections in very-low-birth-weight infants, although without impact on overall mortality.* Thus, in the absence of safety concerns, fluconazole prophylaxis is a valid option for centers with a high frequency (>10%) of invasive *Candida* infections in low-birth-weight infants of less than 1000 g or in the setting of a nosocomial outbreak by a fluconazole-susceptible *Candida* spp. A prospective controlled observational study is still needed to address the neurodevelopmental safety concerns in infants exposed at this young age. Population pharmacokinetics and Monte Carlo simulation support a dose of 3 or 6 mg/kg twice weekly during the first 42 days of life for early prevention of candidiasis in infants born at 23 to 29 weeks of gestation, and a 6-mg/kg dose every 72 hours or 3 mg/kg daily for late prevention.^{57,679,680} In the United States, fluconazole has no pediatric label below 6 months of age, and it is not formally approved for prophylaxis in the neonatal setting¹⁰⁶; in countries of the European Union, the compound is approved for all pediatric age groups with the exception of premature neonates.

Itraconazole

Itraconazole (Sporanox, Sempera; generic forms) is a high-molecular-weight, highly lipophilic triazole (see Fig. 240.5). Structurally related to ketoconazole, it has a broader spectrum of antifungal activity that includes dermatophytes, *Candida* spp. (*C. krusei* excluded), *C. neoformans* and *C. gattii*, *Aspergillus* spp., some non-*Aspergillus* hyalohyphomycetes, various dematiaceous molds, and the dimorphic fungi. Itraconazole binds more avidly to its fungal target than does ketoconazole, but more weakly to human CYP450, thus leading to comparatively fewer mechanism-associated adverse effects.²³⁵

Pharmacodynamics. In vitro, itraconazole exerts species- and strain-dependent fungistatic or fungicidal pharmacodynamics. Time-kill experiments in serum-free and serum-containing media demonstrated the concentration-independent, fungistatic activity of itraconazole against *Candida* spp. and *C. neoformans*.^{94,93,212,740} However, against *Aspergillus* spp., itraconazole displayed time- and concentration-dependent fungicidal activity with 87% to greater than 97% killing within 24 hours of exposure to the drug.⁴¹¹ Potentially relevant persistent effects have not been reported thus far.

*References 57, 67, 75, 114, 120, 186, 277, 333–336, 415, 576, 649.

The principal feasibility of a correlation between in vitro susceptibility and outcome was demonstrated in mice with experimental disseminated aspergillosis.¹⁵³ Relationships between drug concentrations and antifungal efficacy of itraconazole were assessed in a model of invasive pulmonary aspergillosis in methylprednisolone/cyclosporine-immunosuppressed rabbits. In this model, an inhibitory sigmoid maximum effect model predicted a significant pharmacodynamic relationship ($r = .87$, $P < .001$) between itraconazole concentrations in plasma and antifungal efficacy as a function of the burden of *A. fumigatus* in lung tissue.⁶²

In patients, however, the main rationale for monitoring plasma levels has been the erratic oral bioavailability of itraconazole, particularly in neutropenic patients. Historically, the target plasma level for itraconazole has been estimated at 0.25 mg/L (high-performance liquid chromatography [HPLC]) at trough, based on the concentration that inhibits 90% of a large set of clinical isolates.^{81,144} Later, the predictive value of threshold concentrations of prophylactic itraconazole in a large cohort in patients undergoing intensive chemotherapy for acute leukemia was found to be 0.5 mg/L at trough (HPLC) by means of multivariate logistic regression analysis.²²⁴

In a phase I and II clinical trial of oral cyclodextrin-itraconazole in HIV-infected children with oropharyngeal candidiasis, the relationships between pharmacodynamic parameters and therapeutic response as assessed by standardized scoring of mucosal disease after 14 days of therapy fitted to inhibitory maximum effect pharmacodynamic models. Best fits were observed: AUC, AUC/MIC, C_{max} , and C_{max}/MIC ($r = 0.483$ to 0.595 ; $P < .01$).²⁴⁶

Pharmacokinetics. Itraconazole is available as capsules, as oral solution in hydroxypropyl- β -cyclodextrin (HP- β -CD), and as parenteral solution in HP- β -CD³ that has been discontinued in the United States but is available in various other countries. Absorption of itraconazole from the capsule form depends on a low intragastric pH and is compromised in the fasting state, and it becomes erratic in patients with cancer and granulocytopenia or hypochlorhydria.^{125,245,251} Absorption can be somewhat improved when the capsules are taken with food or an acidic beverage.^{143,245} The oral solution of itraconazole in HP- β -CD has improved oral bioavailability that is further enhanced in the fasting state; however, this formulation may cause carrier-associated gastrointestinal intolerance.^{50,547}

After oral administration of the capsule, C_{max} is measured within 1 to 4 hours; following once-daily dosing, steady state is achieved after 7 to 14 days.^{235,245,273} In adult patients with cancer who were receiving the standard regimen of 2.5 mg/kg of HP- β -CD itraconazole twice daily, mean trough levels were 0.8 mg/L under conditions of steady state⁵³²; systemic absorption of the carrier was negligible.¹⁴⁴ After administration of the parenteral solution, drug and carrier rapidly dissociated and followed their own disposition; after the recommended regimen of

200 mg twice daily for 2 days followed by 200 mg daily for 5 days, mean trough levels were 0.53 μ g/mL. The carrier HP- β -CD was not significantly metabolized, and virtually 100% was eliminated from plasma within 24 hours in unchanged form through glomerular filtration.²⁴⁵

Itraconazole exhibits dose-dependent pharmacokinetics with nonlinear increases in the AUC with increasing and split dosages.^{235,246,532} Itraconazole is highly (95%) protein bound; only 0.2% circulates as free drug.²⁸⁸ Although concentrations in nonproteinaceous body fluids are negligible, tissue concentrations in many organs, including the brain, may exceed corresponding plasma levels by 2 to 10 times.^{143,288}

Itraconazole is metabolized extensively in the liver by numerous pathways to more than 30 metabolites and is excreted in metabolized form into bile and urine. The major metabolite, hydroxyitraconazole, possesses antifungal activity similar to that of itraconazole. It is eliminated more rapidly, but its plasma concentrations at steady state are 1.5 to 2 times higher than those of the parent compound.^{144,245,591} The elimination half-life of itraconazole is 20 to 24 hours after single dosing and 35 to 40 hours under terms of steady state, a finding reflecting saturable excretion mechanisms.³⁹⁴ The dosage of oral itraconazole does not need to be adjusted in patients with renal insufficiency or dialysis.⁴⁴⁷ In patients with severe hepatic insufficiency, the elimination half-life of itraconazole can be prolonged, and additional hepatic toxicity or possible drug interactions should be monitored carefully.

Several studies have investigated the pharmacokinetics of the oral HP- β -CD solution of itraconazole in pediatric patients (Table 240.10).^{146,175,246,282,581} In 26 infants and children ages 6 months to 12 years with cancer ($n = 20$) or liver transplantation who received the compound at 5 mg/kg once daily, plasma concentrations were substantially lower than those reported in adult patients with cancer, particularly in children younger than 2 years of age.^{146,532} In 16 neutropenic children (1.7–14.3 years of age) who received HP- β -CD itraconazole for antifungal prophylaxis in a split dosing regimen of 2.5 mg/kg twice daily, peak and trough levels of itraconazole were substantially higher; nonetheless, a similar trend toward lower plasma concentrations occurred in the group of children 5 years of age and younger.⁵⁸¹ In a cohort of 26 HIV-infected children and adolescents (1.25–18 years), HP- β -CD itraconazole was safe and effective for treatment of oropharyngeal candidiasis at dosages of 2.5 mg once per day or 2.5 mg twice daily given for at least 14 days.²⁴⁶ Many (77%) of the patients were receiving concomitant therapy with protease inhibitors or clarithromycin, drugs that are strong inhibitors of the CYP3A4-dependent metabolism of itraconazole.⁵²⁶ Peak and trough levels measured after administration of the split-dosage regimen were similar to those observed in patients with cancer who were receiving the same dosage regimen.⁵⁸¹ Of note, population-based pharmacokinetics in pediatric cystic fibrosis and allogeneic bone marrow transplant patients receiving the oral solution

or the capsule formulation as antifungal prophylaxis suggests a starting dose of 5 mg/kg twice daily.²⁸²

Despite considerable interpatient variability that results from both variable absorption and hepatic metabolism, the pharmacokinetic properties of itraconazole in pediatric patients appear not to be fundamentally different from those of adults. A starting dosage of 2.5 mg/kg twice daily can be advocated, based on the available pharmacokinetic data.^{146,175,246,581} Trough levels should be monitored, and dosing should be adjusted to maintain plasma concentrations of the parent itraconazole of greater than 0.5 mg/L by HPLC.⁷⁰² Of note, itraconazole is not formally approved for pediatric age groups in either the United States or the European Union.

Adverse effects. Itraconazole usually is well tolerated, with a pattern similar to that of fluconazole and a frequency of adverse effects approximately identical to that seen with fluconazole.¹²⁵ In 189 patients treated for systemic fungal infections at dosages of 50 to 400 mg/day for a median of 5 months, the rate of possibly or definitely related adverse effects was 39%.⁶⁴⁷ Most of the observed reactions were transient and included nausea and vomiting (<10%), hypertriglyceridemia (9%), hypokalemia (6%), elevated hepatic transaminases (5%), rash or pruritus (2%), headaches or dizziness (<2%), and pedal edema (1%). Four percent of patients discontinued itraconazole treatment because of adverse effects. Gastrointestinal intolerance is the dose-limiting toxicity of the oral HP- β -CD formulation. In a comparative study in adult patients with acute leukemia, 46% of patients receiving a daily dose of 800 mg stopped treatment early because of severe nausea and vomiting. Crossover to the identical dose of the capsule formulation was well tolerated by all patients; patients receiving 400 mg/day of the solution had no gastrointestinal adverse effects.²²³ Only a few cases of more severe hepatic injury or hepatitis have been described.³⁷⁵ Itraconazole can have negative inotropic effects; because of a low but possible risk for cardiac toxicity, itraconazole should not be administered to patients with ventricular dysfunction.^{9,379}

Cyclodextrin-itraconazole solution was safe and well tolerated for at least 14 days in reported phase I and II pharmacokinetic studies in immunocompromised pediatric patients.^{146,246,581} Vomiting (12%), abnormal liver function tests (5%), and abdominal pain (3%) were the most common adverse effects considered definitely or possibly related to HP- β -CD itraconazole solution in an open study in 103 neutropenic pediatric patients with cancer who received the drug at 5 mg/kg daily or 2.5 mg/kg twice daily for antifungal prophylaxis for a median duration of 37 days; 18% of patients withdrew from the study because of adverse events.²⁰³ In another report on pediatric patients with cancer who were receiving prophylactic oral itraconazole, adverse effects that led to the cessation of the itraconazole prophylaxis occurred in 11% of all 44 courses.⁶⁰³

Drug interactions. In contrast to fluconazole, both the propensity for and the extent of drug-drug interactions are greater.^{242,245} Itraconazole is a substrate of CYP3A4, but it also interacts with the heme moiety of CYP3A, thus resulting in noncompetitive inhibition of oxidative metabolism of many CYP3A substrates. An interaction also can result from inhibition of P-glycoprotein-mediated efflux; P-glycoprotein is extensively co-localized and exhibits overlapping substrate specificity with CYP3A.^{240,261} Inhibition of hepatic CYP450 enzyme systems may lead to increased and potentially toxic concentrations of coadministered drugs. Most important, the coadministration of cisapride, pimozide, bepridil, mizolastine, terfenadine, astemizole, oral midazolam, quinidine, dofetilide, triazolam, sertindole, eletriptan, nisoldipine, and levacetyl-methadol with itraconazole can lead to serious cardiac arrhythmias and is thus strictly contraindicated.^{240,295,526} Similarly contraindicated is the coadministration of 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA)-inhibitor cholesterol-lowering agents such as atorvastatin, lovastatin, and simvastatin, which are associated with rhabdomyolysis,^{240,476} and ergot alkaloids metabolized by CYP3A4, which may result in ergotism. Potentially toxic levels of the coadministered drug also can be reached when itraconazole is given along with phenytoin, carbamazepine, benzodiazepines, cyclosporine, tacrolimus, sirolimus, methylprednisolone, budesonide, digoxin, warfarin, sulfonyleurea compounds, ritonavir, indinavir, haloperidol, clarithromycin, verapamil, felodipine, busulfan, and vinca alkaloids.^{78,240,357,456,486,527,566,665} The interaction between vincristine and itraconazole, which has led to fatalities in some cases, occurs most frequently in the setting of antifungal

prophylaxis. Increased metabolism of itraconazole resulting in decreased plasma levels can be induced by rifampin, rifabutin, isoniazid, carbamazepine, phenobarbital, and phenytoin.^{240,526,646} As a consequence, patients who receive itraconazole along with one of the drugs listed here or in the summary of product characteristics should be followed closely, and plasma concentrations of ideally both compounds, as well as hepatic function, should be monitored carefully.

Clinical indications. The clinical indications for itraconazole are summarized in Tables 240.2 to 240.4, 240.8, and 240.9. Itraconazole is a useful agent for dermatophytic infections,^{115,265} pityriasis versicolor,^{6,208,235,264} vaginal candidiasis,⁶¹⁶ and oropharyngeal and esophageal candidiasis.^{1,146,246,563} While the experience with itraconazole in the primary treatment of cryptococcal meningitis is scant, itraconazole has been used with success for long-term treatment of cryptococcal meningitis in patients with HIV infection.^{562,657}

Itraconazole may be a second-line option for treatment of invasive *Aspergillus* infections, in particular as maintenance or consolidation therapy in non-neutropenic patients.^{155,620} Beyond invasive aspergillosis, itraconazole may be useful in the management of infections by certain dematiaceous molds.^{260,596} Itraconazole is a current treatment of choice for lymphocutaneous sporotrichosis^{145,331,542} and non-life-threatening, nonmeningeal paracoccidioidomycosis, blastomycosis, and histoplasmosis in non-immunocompromised patients.^{112,160,466,474,634,713} as well as induction and maintenance therapy of mild to moderate, nonmeningeal histoplasmosis in HIV-infected patients.^{710,711,713} Although earlier uncontrolled clinical trials suggested a somewhat inferior efficacy against nonmeningeal and meningeal coccidioidomycosis in comparison with fluconazole,^{237,644,645} a randomized, double-blind comparative study in patients with progressive, nonmeningeal coccidioidomycosis showed a trend toward slightly greater efficacy when either of the drugs were given at a daily dosage of 400 mg.²¹⁵ Nonetheless, amphotericin B remains the treatment of choice for endemic mycoses in most immunocompromised patients and for those with life-threatening infections.²⁵¹

Itraconazole was as effective as conventional amphotericin B but better tolerated when used for empirical antifungal therapy in persistently neutropenic patients with cancer.⁸⁰ Prophylactic itraconazole may reduce the incidence of proved or suspected invasive fungal infections in patients with hematologic malignancies⁴³⁷ and those who have undergone HSCT.^{423,726} Efficacy in the prevention of invasive aspergillosis is supported by a large meta-analysis,²²⁵ but not by a randomized, comparative trial.

Posaconazole

Posaconazole (Noxafil) (see Fig. 240.6) is a novel lipophilic antifungal triazole with potent and broad-spectrum activity against opportunistic, endemic, and dermatophytic fungi in vitro. This activity extends to organisms that often are refractory to existing triazoles or amphotericin B or to echinocandins, such as *C. glabrata*, *C. krusei*, *A. terreus*, and *Fusarium* spp. Posaconazole also possesses clinically relevant activity against some members of the order Mucorales both in vitro and in vivo.^{190,260,565,636}

Pharmacodynamics. Posaconazole is considered fungistatic against *Candida* and fungicidal against *Aspergillus* spp.²⁶⁰ In time-kill assays, posaconazole showed concentration- and time-dependent fungicidal activity against *A. fumigatus*.^{248,412,413} In vivo, in a neutropenic kidney target murine model of *C. albicans* infection and in an inhalational murine model of invasive pulmonary aspergillosis, the AUC/MIC ratio was the parameter predictive of antifungal efficacy.^{25,307} In a phase II clinical trial in patients with invasive aspergillosis, higher average plasma concentrations of posaconazole were associated with higher response rates.⁶⁹⁵ Mean plasma concentrations of posaconazole of 719 ng/mL and 1250 ng/mL resulted in overall response rates of 53% and 75% in salvage therapy of invasive aspergillosis.

While pharmacokinetic analysis of the two pivotal prophylaxis trials with the oral suspension did not report significant concentration-effect relationships,^{361,364} a pharmacodynamics assessment performed by the FDA has established an efficacy target for prophylaxis of 700 ng/mL for the purpose of dosing guidance for alternative formulations.³¹⁵

Pharmacokinetics. Posaconazole is available as oral suspension, as solid oral tablet, and as intravenous solution in sulfobutylether-beta-cyclodextrin. The oral suspension achieves optimal exposure when it

is administered in two to four divided doses with food or a nutritional supplement; common gastrointestinal comorbidities in leukemia and hematopoietic stem-cell transplant patients may negatively affect absorption.^{361,364,365} The oral suspension has dose-proportional pharmacokinetics in the 50- and 800-mg dose range, with saturation of absorption occurring at doses higher than 800 mg; after repeat dosing, steady state is achieved after 7 to 10 days with a sixfold to eightfold accumulation of plasma concentrations,¹³⁵ and marked accumulation within alveolar cells of the lung.¹²⁶ The solid oral tablet contains a pH-sensitive polymer matrix that inhibits the release of posaconazole prior to reaching the small intestine; it confers enhanced bioavailability and less variability in exposure, and gastric filling, pH and motility have no effect on absorption.^{356,362,363} In a phase IB dose-ranging multicenter study in adults, a dose of 300 mg once daily (day 1: 300 mg twice daily) attained the prespecified exposure target of a C_{average} of between 500 and 2500 ng/mL in 97% of the 51 subjects¹⁷⁷; in a subsequent phase III study in adult patients at high risk for invasive fungal disease, the tablet formulation demonstrated a safety profile similar to that reported for posaconazole oral suspension, and most of the 210 patients (99%) achieved steady-state C_{average} exposures in plasma of greater than 500 ng/mL.¹²⁹ Likewise, in a phase IB dose-ranging multicenter study in adults, 300 mg once daily (day 1: 300 mg twice daily) of the intravenous solution attained the prespecified exposure target in 95% of patients.⁴⁰³ However, when administered peripherally at the same infusion site, multiple dosing of intravenous posaconazole led to unacceptably high rates of infusion-site reactions.³³⁷ Independent of the formulation, posaconazole has a large volume of distribution in the order of 5 L/kg and displays a prolonged elimination half-life of approximately 20 hours. Posaconazole is metabolized to a small extent by uridine diphosphate (UDP) glucuronidation; it is not significantly metabolized through the CYP450 enzyme system but is primarily excreted in unchanged form in the feces (Table 240.11).^{260,360,709} Posaconazole is a substrate and inhibitor of P-glycoprotein. However, investigation of the relationship between human multidrug resistance gene (*MDR1*) mRNA expression and posaconazole exposure showed no correlation. Thus, the moderate variability in the compound's pharmacokinetics is unlikely to be caused by interindividual differences in P-glycoprotein expression.¹³⁶

Adverse effects. The overall safety of posaconazole was assessed in two open-label clinical trials of more than 400 patients with invasive fungal infections who received posaconazole suspension 800 mg/day in divided doses. Treatment-related adverse events occurred in 38% of patients (164 of 428); the most common were nausea (8%), vomiting (6%), headache (5%), abdominal pain (4%), and diarrhea (4%). Treatment-related abnormal liver function test results were observed in 3% of patients. No clinically significant differences occurred in mean QTc interval change from baseline. Serious adverse events considered possibly or probably related to posaconazole occurred in 35 (8%) patients. The most common severe adverse events were altered drug level, increased hepatic enzymes, nausea, rash, and vomiting (1% each). No significant trends related to age, sex, or race were observed, and no unique treatment-related adverse events were identified in patients during long-term

exposure (>6 months) in contrast to those identified during shorter-duration therapy.^{505,536} In two large, prospective, randomized comparative clinical trials investigating posaconazole for prevention of invasive fungal infections in high-risk patients with leukemia or HSCT, posaconazole was well tolerated, and the rate of study drug discontinuations in posaconazole-treated patients was not different from that in subjects in the control cohort receiving fluconazole or itraconazole.^{132,650}

Drug interactions. Posaconazole is not significantly metabolized through the CYP450 enzyme system; therefore, CYP450-mediated drug-drug interactions have limited potential to affect posaconazole pharmacokinetics.³⁶⁰ Posaconazole is a potent inhibitor of cytochrome P3A4, but it has no effect on 1A2, 2C8, 2C9, 2D6, or 2E1 isoenzymes.⁷⁰⁹ Concomitant administration of posaconazole with terfenadine, astemizole, cisapride, pimozide, halofantrine, and quinidine can lead to serious cardiac arrhythmias and is thus strictly contraindicated.^{572,573} Similarly contraindicated is the coadministration of HMG CoA-inhibitor cholesterol-lowering agents such as atorvastatin, lovastatin, and simvastatin, which are associated with rhabdomyolysis, and ergot alkaloids metabolized by CYP3A4, which may result in ergotism. Potentially toxic levels of the coadministered drug can be reached when posaconazole is given along with phenytoin, carbamazepine, benzodiazepines, cyclosporine, tacrolimus, sirolimus, methylprednisolone, digoxin, warfarin, sulfonyleurea compounds, ritonavir, indinavir, atazanavir, haloperidol, clarithromycin, verapamil, nifedipine, diltiazem, nisoldipine, rifabutin, and vinca alkaloids. Because of a relevant decrease in posaconazole concentrations, concomitant use with rifabutin, phenytoin, efavirenz, fosamprenavir, cimetidine, or esomeprazole should be avoided.^{91,572,573}

Clinical efficacy. Posaconazole has been targeted for prevention and treatment of serious infections caused by opportunistic and endemic fungal organisms. Posaconazole has demonstrated strong antifungal efficacy in phase II clinical trials in immunocompromised patients with primary or refractory oropharyngeal and esophageal candidiasis.^{606,666} In a randomized, comparative phase III trial, posaconazole 100 mg daily (with day 1 dose 200 mg) was as effective as was fluconazole 100 mg daily (with day 1 dose 200 mg), in the primary treatment of HIV-associated oropharyngeal candidiasis: 155 of 169 (91.7%) patients receiving posaconazole in contrast to 148 of 160 (92.5%) of patients receiving fluconazole achieved a complete clinical response (cure).⁶⁶⁷ Posaconazole 800 mg in divided doses also was investigated as salvage therapy in a large phase II study including 330 patients with invasive fungal infections intolerant to or refractory to standard therapies and a contemporaneous external control of 279 patients.⁵³⁵ Most patients (86%) were refractory to previous therapy. Successful outcomes at the end of treatment in the posaconazole cohort and in the contemporaneous external control cohort were 42% versus 26% in aspergillosis (107 and 86 patients; separately published⁶⁹⁵), 39% versus 50% in fusariosis (18 vs. 4 patients), 56% versus 50% in zygomycosis (11 vs. 8 patients), 69% versus 43% in coccidioidomycosis (16 vs. 7 patients), 52% versus 53% in candidiasis (23 vs. 30 patients), 48% versus 58% in cryptococcosis (31 vs. 64 patients), 81% versus 0% in chromoblastomycosis (11 vs. 2 patients), and 64% versus 60% in other invasive fungal infections (30

UDP-GT, UDP glucuronosyltransferase.

vs. 20 patients). In a subset analysis of 39 patients with mostly refractory proved or probable CNS infections, posaconazole demonstrated clinical efficacy against cryptococcal meningitis (success rate in 29 patients [48%]) and against infections caused by opportunistic or endemic molds (5 of 10 patients [50%]).^{527,535} These data are in agreement with the compound's extended spectrum of activity in vitro and demonstrate efficacy for treatment of refractory invasive opportunistic and endemic mycoses. A retrospective analysis of the manufacturer's compassionate-use program including 91 patients with proved or probable mucormycosis refractory or intolerant to prior antifungal therapy revealed a 60% success rate (complete and partial responses) at 12 weeks after initiation of therapy, thus providing first evidence for the clinical utility of posaconazole as second-line or consolidation therapy of mucormycosis.⁶⁵³ Posaconazole has also been shown in a randomized, placebo- and active-controlled multicenter trial to be effective against toenail onychomycosis.¹⁸³

The use of posaconazole for antifungal prophylaxis has had an important impact on reducing mortality of invasive fungal infections in patients with acute leukemia.²⁶⁸ Two pivotal preventive randomized phase III studies in high-risk patients with HSCT and GVHD⁶⁵⁰ and acute leukemias¹³² have been conducted. In the first study, patients received either posaconazole 200 mg three times daily or fluconazole 400 mg daily, respectively, with the start of immunosuppression for a total of 16 weeks. Treatment with posaconazole led to a decreased incidence of invasive fungal infections at 16 weeks (5% vs. 9%; $P = .07$), with a statistically significant decrease in invasive *Aspergillus* infections (2% vs. 7%; $P = .006$). Seven days after end of treatment, fewer patients had invasive fungal disease (2% vs. 8%; $P = .004$) and fewer patients had invasive aspergillosis (1% vs. 6%; $P = .001$). No differences in overall mortality rates occurred at 12 weeks.⁶⁵⁰ In the second study, patients received posaconazole 200 mg three times daily and either fluconazole 400 mg daily or itraconazole 200 mg twice daily, respectively. Treatment was started with each cycle after a drop of the absolute neutrophil count (ANC) to 500/ μ L or less for up to 12 weeks. Significantly fewer patients enrolled in the posaconazole arm of the trial developed an invasive fungal infection at day 7 after the end of treatment in contrast to the comparator arm (2% vs. 8%; $P = .01$); most important, treatment with posaconazole resulted in a significant decrease in the rate of invasive aspergillosis (1% vs. 7%; $P = .001$). At day +100 after randomization, the rate of invasive fungal infections was 5% and 11% ($P = .01$), respectively, and patients treated with posaconazole had a significantly improved survival probability ($P = .035$).¹³² These two important studies demonstrate the preventive efficacy of posaconazole, in particular against invasive *Aspergillus* infections in high-risk patients, and a statistically significant survival benefit in patients with acute myeloblastic leukemia/myelodysplastic syndrome who are undergoing remission induction chemotherapy.

Approval status and dosing. In the United States, posaconazole is approved for treatment of oropharyngeal candidiasis, including disease refractory to itraconazole or fluconazole (oral suspension), and for prophylaxis of invasive *Candida* and *Aspergillus* infections in high-risk patients 13 years of age and older with HSCT and GVHD or those with hematologic malignancies and prolonged neutropenia (oral suspension and delayed-release tablets; intravenous solution for subjects ≥ 18 years). In the European Union, the compound is similarly approved for prophylaxis in high-risk adult patients, but also for treatment of aspergillosis, fusariosis, chromoblastomycosis, and coccidioidomycosis refractory to or intolerant of standard therapies in patients 18 years of age and older (see Tables 240.3, 240.4, and 240.9).

The recommended doses in patients 18 years of age and older for primary treatment of oropharyngeal candidiasis with the oral suspension is 100 mg/day (with day 1 dose 100 mg twice daily) and 400 mg twice daily for refractory disease; for prophylaxis of invasive *Candida* and *Aspergillus* infections, the recommended dose is 200 mg of the suspension three times daily or 300 mg once daily of the delayed-release tablets and the intravenous solution, respectively, with a loading dose of 300 mg twice daily on day 1 for each formulation. The dose of the oral suspension for salvage treatment is 400 mg twice daily given with food; for patients not tolerating solid food, the delayed-release tablets or the intravenous solution may be given at the identical doses as used for antifungal

prophylaxis. Because of the improved target attainment, the delayed-release tablets should preferentially be administered when posaconazole is given by the oral route.⁶⁹⁴

Current data indicate no need for adjustments to dosage based on differences in age, gender, race,⁵⁷⁴ or renal or hepatic function.^{137,134} The pharmacokinetic properties of posaconazole in pediatric patients (<18 years of age) have not been conclusively studied. Early data obtained in 12 pediatric patients 8 years of age and older receiving the oral suspension indicated no fundamental differences in trough plasma concentrations in contrast to that of adults.³⁶⁵ A twice-daily dosing algorithm based on allometric scaling for posaconazole resulted in adequate exposure in children with chronic granulomatous disease.⁷⁰⁷ However, similar to published clinical experiences,^{66,429,664} a pediatric phase IB dose finding trial was discontinued for failure to achieve the pharmacokinetic target due to absorption issues.³⁶ The intravenous solution and a new oral suspension formulation are currently under clinical investigation in order to provide pharmacokinetic and safety data on which to base safe and effective dosing of this important compound to pediatric patients.

Despite the described problems with absorption, successful salvage treatment with posaconazole has been reported in small numbers of pediatric patients with invasive fungal infections.^{74,381} In these and other reports, posaconazole oral suspension was well tolerated and safe without signals for increased or unexpected toxicities relative to the adult population.*

Voriconazole

Voriconazole (Vfend; generic forms) (see Fig. 240.6) is a synthetic antifungal triazole with activity against a wide spectrum of clinically important yeasts and molds, including *Candida* spp., *C. neoformans*, *Aspergillus*, and other hyaline molds, dematiaceous molds, and dimorphic molds, both in vitro and in animal models. A notable exemption is the Mucorales, against which voriconazole is intrinsically inactive.^{242,323,321,460}

Pharmacodynamics. Against *Candida* spp. and *C. neoformans*, voriconazole exhibited non-concentration-dependent fungistatic activity; against *A. fumigatus*, voriconazole displayed time-dependent fungicidal activity.^{340,411} A concentration-dependent PAFE of 0.2 to 4.1 hours has been observed in the presence of serum against *C. albicans*.²¹⁶ In a murine kidney target model of disseminated candidiasis, the AUC/MIC ratio was the pharmacodynamic parameter that correlated best with efficacy. Using 10 *C. albicans* isolates of different voriconazole susceptibilities, the free drug AUC/MIC ratios were similar to all the organisms studied and similar to those observed for other azoles.²⁶ The AUC/MIC ratio also correlates with antifungal activity in vitro against *A. fumigatus*.³¹⁷ Concentration-response relationships of voriconazole in patients were analyzed in a total of 825 subjects from nine previously published clinical trials using logistic regression and Monte Carlo simulation. Whereas logistic regression analysis showed a nonlinear concentration-response relationship with the probability lower at the extremes, Monte Carlo simulation revealed that a trough/MIC ratio of 2:5 was associated with a near-maximal probability of response and that this parameter can be used as the exposure target, on the basis of either an observed MIC or reported MIC₉₀ values of the suspected fungal pathogen(s).⁶⁴³

Pharmacokinetics. Voriconazole is available in oral and intravenous formulations. Oral bioavailability exceeds 90% in adults in the fasted state, but it is considerably lower (65%) in children,⁶⁸³ which may be due to intestinal first-pass metabolism.⁷³⁷ In adults, the compound has nonlinear pharmacokinetics between the dosages of 3 mg/kg and 4 mg/kg, while being linear in this dosage range in children.^{683,690} Plasma protein binding is 58%, and the mean volume of distribution accounts for 2 L/kg. Tissue and CSF levels may exceed trough plasma levels severalfold. The plasma half-life is 6 hours, with elimination occurring primarily by oxidative hepatic metabolism to at least eight metabolites that are eliminated through the urine; less than 2% of a dose of voriconazole is excreted unchanged in urine. The major isoenzyme involved in voriconazole metabolism is CYP2C19, but CYP2C9 and CYP3A4 also contribute (see Table 240.11). In addition to considerable intrasubject variability, wide between-subject variability exists in the disposition of

*References 36, 66, 74, 135, 164, 165, 365, 381, 429, 664, 707, 736.

voriconazole that is at least in part related to a genetic CYP2C19 polymorphism.^{242,289,455,523,533} The latter may be particularly relevant in Japanese patients, who have a higher incidence of poor and intermediate metabolizer phenotypes.⁴⁶⁷ Recent guidelines from the Clinical Pharmacogenetics Implementation Consortium (CPIC) provide evidence-based recommendations for therapeutic drug monitoring or use of an alternative antifungal agent depending upon the CYP2C19 genotype.⁴⁵⁷ Based on this variability, the significant correlations between exposure and effect,⁶⁴³ and significant effects of therapeutic drug monitoring on treatment responses and adverse effects,^{401,501} therapeutic drug monitoring is advocated in patients with life-threatening invasive fungal infections with a target trough concentration of between 1 and 5 mg/L of voriconazole, depending on safety and tolerability.^{388,401,638,643}

Adverse effects. Voriconazole has an acceptable safety profile. The accrued clinical data indicate that side effects include four distinct clinical categories: transient liver enzyme abnormalities (10–20%), skin reactions (<10%), visual hallucinations or confusion (<10%), and transient, dose-related visual disturbances (photopsia with altered or enhanced perception of light, blurred vision; 25% to 45%).²⁴² With regard to the visual disturbances, no morphologic correlation was noted in animal models, and the underlying mechanism remains to be elucidated.³²¹ Drug-related adverse effects requiring the discontinuation of voriconazole were infrequent in comparative clinical trials and ranged from 2% to 13%.^{12,284,693}

Serious hepatic reactions, including hepatic failure, have been observed during treatment with voriconazole; therefore, evaluation of liver function tests before and during treatment with voriconazole is advised. Azole therapy has been associated with QTc prolongation; for this reason, voriconazole should be administered with caution to patients with proarrhythmic conditions.²⁴² Phototoxicity is relatively common in children and has been reported to occur in close to 50% of children treated for 6 months or longer.⁵⁹⁷ A possible link between long-term use of voriconazole, immunosuppression, and chronic phototoxicity with aggressive squamous cell carcinoma and melanoma has been reported in adult and pediatric patients.^{138,443,597,728} As a consequence, the indication for further and prolonged voriconazole treatment in immunocompromised patients who develop phototoxicity needs to be evaluated extremely carefully.⁵⁹⁷ Caution is also warranted with the concurrent use of methotrexate, as severe skin toxicity has been observed.⁶⁶¹ Moreover, fluorosis and periostitis also have been reported during long-term voriconazole use because of its elevated fluoride content.^{625,708} Voriconazole is teratogenic in animals and may cause fetal harm when it is administered to a pregnant woman.²⁴²

Drug interactions. Voriconazole is both substrate and inhibitor of CYP2C19, CYP2C9, and CYP3A4, and, therefore, numerous clinically relevant and potentially hazardous drug-drug interactions must be considered and the drug product label consulted.^{240,242} Voriconazole significantly increases exposure to cyclosporine, tacrolimus, benzodiazepines, methadone, fentanyl, alfentanil, oxycodone, vinca alkaloids, statins, omeprazole, warfarin, sulfonyleurea drugs, phenytoin, protease inhibitors other than indinavir, and non-nucleoside reverse transcriptase inhibitors, thus requiring dosage adjustment or monitoring. Voriconazole exposure is significantly decreased by St. John's wort, phenytoin, ritonavir, efavirenz, rifabutin, carbamazepine, rifampin, and phenobarbital. Concurrent use of the last three enzyme inducers with voriconazole is contraindicated (risk for subtherapeutic levels of voriconazole), as is the concurrent use of terfenadine, astemizole, cisapride, quinidine, pimozide (risk of QTc prolongation resulting from increased exposure to these agents), ergotamine (risk for ergotism resulting from increased exposure), and sirolimus (increased exposure). Although voriconazole and sirolimus are relatively contraindicated due to the precipitous and approximately 10-fold rise of sirolimus, the combination may be used with 90% initial dosage reduction of the m-TOR inhibitor and with careful therapeutic drug monitoring of both agents. Dosage adjustments of voriconazole are also necessary when the drug must be used concurrently with phenytoin or rifabutin.^{91,240,242,321,346}

Clinical efficacy. Voriconazole has demonstrated excellent clinical efficacy in phase II and III clinical trials in patients with oropharyngeal candidiasis and esophageal candidiasis.^{12,280} In salvage studies in patients with fungal infections refractory or intolerant to treatment, complete

and partial responses were seen in 43% to 48% of patients with invasive aspergillosis,^{154,508,690} in 45% to 52% of patients with invasive candidiasis,⁵⁰⁸ in 30% to 63% of patients with scedosporiosis,^{508,690} in 45% of patients with fusariosis,⁵⁰⁸ and in 38% of patients with cryptococcosis.⁵⁰⁸

A large, multinational, randomized phase III clinical trial of voriconazole and amphotericin B deoxycholate followed by other licensed antifungal agents for primary therapy of invasive aspergillosis revealed superior outcomes in voriconazole-treated patients.²⁸⁴ At week 12, successful outcomes were noted in 52.8% of the patients in the voriconazole group and in 31.6% of those in the amphotericin B group (absolute difference, 21.2 percentage points; 95% confidence interval [CI], 10.4 to 32.9). The survival rate at 12 weeks was 70.8% in the voriconazole group and 57.9% in the amphotericin B group (hazard ratio, 0.59; 95% CI, 0.40–0.88). Voriconazole-treated patients had significantly fewer severe drug-related adverse events. A randomized double-blind clinical trial comparing open-label voriconazole plus blinded anidulafungin or blinded placebo for treatment of proved or probable invasive aspergillosis in patients with hematologic malignancies or allogeneic HSCT showed a statistical trend ($P = .07$) favoring the combination therapy with respect to the overall survival at 6 weeks, the primary endpoint of the study.⁴²⁵ In a post-hoc analysis of patients diagnosed on the basis of positive galactomannan, which accounted for 78% of the study population, overall survival at 6 weeks was significantly higher in the combination arm. Although the clinical implications of this study are still debated, regulatory approval of the combination for invasive aspergillosis has failed. A randomized comparative study of voriconazole versus amphotericin B deoxycholate followed by fluconazole for treatment of candidemia in non-neutropenic patients showed similar response rates at end of treatment and similar survival rates at 3 months.³⁶⁷ Twelve weeks after the end of treatment, successful outcomes were observed in 41% of patients in both treatment groups. Voriconazole cleared blood cultures as quickly as amphotericin B/fluconazole, and significantly fewer serious adverse events and cases of renal toxicity occurred. In a large, international collaborative study of voriconazole versus liposomal amphotericin B for empirical therapy, voriconazole did not meet the prespecified statistical endpoint for non-inferiority in a composite endpoint but was associated with significantly fewer breakthrough invasive fungal infections, particularly those caused by invasive aspergillosis.⁶⁹³ Finally, several reports also suggested the potential usefulness of voriconazole for treatment of infections by unusual hyaline and dematiaceous fungi,⁵⁰⁸ as well as for treatment of cerebral mold infections.⁵⁸⁸

Voriconazole also has been investigated as primary antifungal prophylaxis.^{421,721} A multicenter, randomized, double-blind trial compared voriconazole 200 mg twice daily to fluconazole 400 mg once daily in 600 adult allogeneic HSCT patients. There was no difference in the cumulative rates of proved, probable, and presumptive invasive fungal infections at 6 months (7.3% vs. 11.2% [$P = .12$]); however, a trend was noted toward fewer infections by *Aspergillus* (9% vs. 17%, $P = .09$). Fungus-free survival rates (78% and 75%, respectively) were similar, as were overall survival rates and rates of premature study drug withdrawal.⁷²¹ A second study compared voriconazole 200 mg twice daily to itraconazole 200 mg twice daily in 489 allogeneic HSCT recipients. Efficacy was assessed by a composite endpoint, including survival at 180 days after transplantation and no breakthrough infections and no discontinuation of the study drug for more than 14 days during the first scheduled 100 days. Using this endpoint, voriconazole was superior to itraconazole, with a 49.1% versus 34.5% success rate ($P = .0004$). However, the rate of proved and probable invasive fungal infections was low (3% vs. 6%).⁴²¹

Approval status and dosing. Voriconazole is approved in the United States and the European Union for treatment of invasive aspergillosis, fusariosis, and scedosporiosis; treatment of esophageal candidiasis; and primary treatment of candidemia and certain forms of invasive candidiasis in non-neutropenic patients (see Tables 240.2 and 240.3).^{109,194} The recommended intravenous dosages for adults and adolescents (12 to 14 years and ≥ 50 kg; 15 to 17 years regardless of body weight) are 6 mg/kg twice daily on day 1, followed by 4 mg/kg twice daily. Oral doses in adults are 400 mg twice daily on day 1 (≥ 40 kg, 200 mg twice daily), followed by 200 mg twice daily (<40 kg, 100 mg twice daily).¹⁹⁴

TABLE 240.12 Simulated Plasma Concentrations of Voriconazole After Multiple Doses of 3 and 4 mg/kg in Pediatric Versus Adult Patients

Parameter	VALUE ^a			
	Pediatric Patients (2–11 y)		Adult Patients	
	3 mg/kg	4 mg/kg	3 mg/kg	4 mg/kg
AUC _{tau} (ng/h/mL)	10,670	14,227	13,855	38,605
C _{average} (ng/mL)	889	1,186	1,155	3,217

^aData are reported as medians following 6 mg/kg every 12 hours on day 1 and maintenance dose 3.

Whereas in pediatric patients, an increase in dosage by a factor of 1.3 leads to proportional increase in the mean average plasma concentration (C_{average}) and in the mean area under the concentration versus time curve (AUC_{tau}), adult patients display a 2.8-fold, hyperproportional increase in exposure, indicating nonlinear disposition. As a consequence, pediatric patients given 4 mg/kg do not achieve the same exposure as adults given 4 mg/kg, the dosage that has led to the approval of voriconazole for first-line treatment of invasive aspergillosis.

Modified from Walsh TJ, Karlsson MO, Driscoll T, et al. Pharmacokinetics and safety of intravenous voriconazole in children after single- or multiple-dose administration. *Antimicrob Agents Chemother*. 2004;48:2166–2172.

In patients with renal insufficiency, no adjustment of dosage is needed for the oral formulation; because of the renal clearance of the intravenous carrier, patients with a creatinine clearance of less than 50 mL/min should receive voriconazole by the oral route. In patients with mild-to-moderate hepatic function abnormalities, half of the daily maintenance dosage is recommended after the initial loading dose. Recommendations for severe liver failure are lacking.^{242,321}

Whereas the disposition of voriconazole in infants younger than 2 years of age has not been systematically investigated,¹⁶¹ initial pharmacokinetic studies in children 2 to 11 years of age revealed a faster weight-normalized clearance rate than in adults and lower exposure at similar dosages (Table 240.12).⁶⁸⁹ This and several subsequent formal pharmacokinetic studies revealed that children need higher exposures relative to adults and that young adolescents 12 to 14 years of age with low body weight (<50 kg) appear to metabolize voriconazole similarly to children.^{173,174,207,329,683} As a consequence, an intravenous dosage of 8 mg/kg twice daily (with day 1 dose 9 mg/kg twice daily) and an oral dose of the suspension of 9 mg/kg twice daily has been adopted by the European Medicines Agency (EMA) for children 2 years of age to younger than 12 years and 12 to 14 years weighing less than 50 kg.^{194,207} Of note, the pediatric dosing regimens outlined here have also been explored in Japanese patients and found to be appropriate for this special population.⁴⁵³ Considering the significant relationships between exposure and outcome described earlier, therapeutic drug monitoring should be performed in pediatric patients with life-threatening invasive fungal infections.^{239,388,401,473}

Voriconazole has been administered safely and successfully to children younger than 12 years of age who had no therapeutic alternative. Of 58 immunocompromised children with proven or probable invasive fungal infection refractory to or intolerant of conventional antifungal therapy, 26 patients (45%) had a complete or partial response and 4 patients (7%) discontinued therapy because of intolerance. A total of 23 patients had voriconazole-related adverse events, most commonly elevations in hepatic transaminases or bilirubin (*n* = 8), skin rash (*n* = 8), abnormal vision (*n* = 3), and photosensitivity reactions (*n* = 3).⁶⁹⁰ A large retrospective post-approval cohort study in 107 immunocompromised pediatric patients who received 252 courses of voriconazole for a median of 65 days (range, 1–1001) reported further safety data. Irrespective of causal relationships, increases in hepatic transaminases (53.5%), serum bilirubin (23.6%), and alkaline phosphatase (10.9%), skin eruptions (5.6%), and neurologic adverse events (4.8%) were mostly mild to moderate. Adverse events necessitating discontinuation of

voriconazole occurred in 18 courses (7.1%). Treatment success was observed in 16 of 37 patients with proved, probable, or possible infections, and in 203 of 215 courses of empirical therapy or prophylaxis.⁵²⁴ In other pediatric studies providing sufficient information, the rate of drug discontinuations because of adverse events was between 5% and 19%. Increases in hepatic transaminases were the most commonly observed adverse events, followed by skin eruptions, and no consistent correlation between dose or exposure and adverse events have been established.¹⁶³ Voriconazole also has been used with success and acceptable tolerance in many patients with cystic fibrosis and allergic bronchopulmonary aspergillosis²⁹¹ and as antifungal prophylaxis in patients with hematologic malignancies or allogeneic HSCT.^{164,414,422,449,736}

Isavuconazole

Isavuconazonium sulfate (Cresemba) is the water-soluble prodrug of isavuconazole, a broad-spectrum antifungal triazoles with activity against yeasts, molds, and dimorphic fungi. Isavuconazole is available as intravenous solution and as capsules for oral administration and approved for treatment of invasive aspergillosis and mucormycosis.^{105,193,439}

Pharmacodynamics. Similar to other members of its class, isavuconazole is considered fungistatic against yeasts and mostly fungicidal against opportunistic moulds.⁴³⁹ In vitro, prolonged antifungal effects of up to 5 hours duration have been demonstrated against *C. albicans*.⁷⁰¹ In a neutropenic murine model of disseminated candidiasis, the AUC/MIC ratio was the pharmacodynamic index that correlated best with efficacy. Pharmacodynamic targets for *C. albicans* were similar to those observed with other triazoles; however, targets for non-*albicans* *Candida* species were more than 10-fold lower than those for *C. albicans*.³⁸⁵ In a persistently neutropenic rabbit model of invasive pulmonary aspergillosis, isavuconazole demonstrated dosage- and concentration-dependent response in reducing mortality, organism-mediated pulmonary injury, residual fungal burden, serum galactomannan index (GMI), and serum (1→3)-β-D-glucan levels.⁵¹² Within the same model system, the AUC/MIC ratio correlated with suppression of the galactomannan index (GMI), and bridging of this experimental pharmacodynamic target to human population PK data showed the applicability of this efficacy endpoint for patients with invasive aspergillosis.³⁵² Similarly, using population pharmacokinetic data, Monte Carlo simulations, and the non-neutropenic murine efficacy index corresponding to 90% survival, isavuconazole exposures were achieved in >90% of simulated patients to treat MICs up to and including 1 mg/L according to EUCAST methodology, and >90% up to and including 0.5 mg/L according to CLSI methodology, respectively.¹⁵⁶ These investigations confirm the current dosing regimen and are helpful in setting interpretive breakpoints for in vitro resistance testing.

Pharmacokinetics. After systemic administration, the prodrug isavuconazonium sulfate is converted by plasma esterases to isavuconazole and the inactive cleavage product. The conversion is rapid and complete, with greater than 98% of a dose being converted to isavuconazole. The cleavage product is eliminated by metabolism and subsequent renal excretion of the metabolites.^{105,193,439} In pharmacokinetic studies in healthy volunteers, maximum plasma concentrations (C_{max}) of isavuconazole were observed at 1.5 to 3 hours after oral administration or at the end of the 1-hour infusion. C_{max} and AUC values increased proportionally to the administered dose; there was a four- to fivefold accumulation during once-daily dosing, which is in line with the long terminal elimination half-life of isavuconazole of 84.5 to 117 hours, and the oral bioavailability was calculated at 98%. At steady state, after daily doses of 50 and 100 mg, the volume of distribution amounted to 308 to 542 L and systemic clearance was 2.4 to 4.1 L/h.^{582,583} In a population-based pharmacokinetic model including data from nine phase I and one phase III clinical trial, a 2-compartment model with Weibull absorption function and first-order elimination process adequately described plasma isavuconazole concentrations; the mean estimate for isavuconazole clearance was 2.36 L/h, and those for the volumes of the central and peripheral compartments 49.1 and 417 L, respectively.¹⁵⁶ Isavuconazole is metabolized by the liver and excreted in metabolized form into urine and feces; in vitro studies indicate that CYP3A4, CYP3A5, and subsequently uridine diphosphate-glucuronosyltransferases (UGT) are involved.^{109,193}

Adverse effects. Among 403 patients enrolled in two registration-relevant clinical trials, the most frequently reported adverse reactions of isavuconazole were gastrointestinal disturbances (13–26%), headache (17%), elevated liver chemistry tests (16%), hypokalemia (14%), dyspnea (12%), cough (12%), peripheral edema (11%), and back pain (10%). Serious adverse reactions occurred in 223 of 403 (55%) of patients, and 56 of 403 (14%) of patients permanently discontinued treatment due to an adverse reaction.¹⁰⁵ In trial 1, a randomized, double-blind comparison of isavuconazole (200 mg intravenously three times a day on days 1 and 2, then either intravenously or orally once daily) versus voriconazole (6 mg/kg intravenously twice daily on day 1, 4 mg/kg intravenously twice daily on day 2, then intravenously 4 mg/kg twice daily or orally 200 mg twice daily from day 3 onwards), most patients (247 [96%] receiving isavuconazole and 255 [98%] receiving voriconazole) had treatment-emergent adverse events ($P = .122$). Proportions of patients with treatment-emergent adverse events by system organ class were similar overall. However, isavuconazole-treated patients had a lower frequency of hepatobiliary disorders (23 [9%] vs. 42 [16%]; $P = .016$), eye disorders (39 [15%] vs. 69 [27%]; $P = .002$), and skin or subcutaneous tissue disorders (86 [33%] vs. 110 [42%]; $P = .037$). Drug-related adverse events were reported in 109 (42%) patients receiving isavuconazole and 155 (60%) receiving voriconazole ($P < .001$). In this pivotal trial, isavuconazole was well tolerated, with fewer study-drug-related adverse events relative to voriconazole.⁴⁰⁸

Drug interactions. Isavuconazole is a substrate of CYP3A4 and CYP3A5. In vitro, isavuconazole is an inhibitor of CYP3A4, CYP2C8, CYP2C9, CYP2C19, and CYP2D6. Isavuconazole is also an inhibitor of P-gp-, BCRP- and OCT2-mediated drug transporters. In vitro, isavuconazole is also an inducer of CYP3A4, CYP2B6, CYP2C8, and CYP2C9.^{105,193,241} Because of the lack of a pediatric label, a detailed description of drug-drug interactions of isavuconazole is beyond the scope of this chapter, and the respective drug product label with the full prescribing information should be consulted.

Clinical efficacy. The clinical efficacy of isavuconazole has been investigated in phase II and III clinical trials in patients with uncomplicated esophageal candidiasis, candidemia or invasive candidiasis, and invasive mold disease caused by *Aspergillus* and other filamentous fungi, as well as those causing mucormycosis.^{736,689,699,702}

In a dose-ranging phase II trial of isavuconazole in 160 patients with uncomplicated esophageal candidiasis evaluating different dosing regimens of isavuconazole and fluconazole 100 mg once daily (day 1: 200 mg), endoscopically confirmed clinical success rates after a minimum of 14 days of treatment were similar to those of fluconazole for each arm; there were no differences in the percentages of relapse at day 28 post end of treatment.⁶⁷³ The efficacy and safety of isavuconazole in patients with candidemia and other forms of invasive candidiasis were investigated in a phase III randomized, double-blind trial comparing isavuconazole 200 mg IV three times daily for 2 days, followed by 200 mg IV daily versus caspofungin (70 mg IV daily on day 1, followed by 50 mg IV daily) with the option for a switch to oral isavuconazole (isavuconazole arm) or voriconazole (caspofungin arm) after day 10. The primary efficacy endpoint was successful overall response (based on successful clinical and mycological responses, and no use of alternative systemic antifungal therapy post end of treatment) at the end of IV therapy (EOIV). Among 400 evaluable patients, the primary endpoint of successful overall response at EOIV (isavuconazole, $n/N = 120/199$ [60.3%]; caspofungin, $n/N = 143/201$ [71.1%]; adjusted difference [95%CI]: -10.8 [$-19.9, -1.8$]) did not meet the prespecified non-inferiority margin. However, key secondary endpoints, all-cause mortality, and other outcomes including safety were similar in both arms.³⁶⁸

The efficacy of isavuconazole against invasive aspergillosis was studied in a phase III, double-blind, randomized trial. Adult patients with suspected invasive mold disease were randomized to receive 200 mg isavuconazole intravenously three times a day on days 1 and 2, then either intravenously or orally once daily or voriconazole 6 mg/kg intravenously twice daily on day 1, 4 mg/kg intravenously twice daily on day 2, then intravenously 4 mg/kg twice daily or orally 200 mg twice daily from day 3 onward. A total of 527 adult patients were randomly assigned (258 received study medication per group); all-cause mortality from first dose of study drug to day 42 was 19% with isavuconazole

and 20% with voriconazole with an adjusted treatment difference of -1.0% (95% CI -7.8 to 5.7), meeting criteria for non-inferiority. In the cohort of 231 patients who had proven or probable invasive aspergillosis, all-cause mortality was 18.7% in the isavuconazole arm and 22.2% in the voriconazole arm, respectively, with an adjusted treatment difference of -2.7% (95% CI -13.6 to 8.2). Overall treatment success for proven/probable invasive aspergillosis at end of therapy was 35.0% (43/123) versus 38.9% (42/108) (95% CI, -16.3 to -8.4], not significant).

Isavuconazole was as effective as voriconazole and well tolerated with fewer study-drug-related adverse events relative to voriconazole.⁴⁰⁸ The efficacy of isavuconazole for treatment of mucormycosis was assessed in a single-arm open-label phase III trial (VITAL study) using the identical dosing regimen as before and compared with amphotericin B in a matched case-control analysis. In this study, 37 patients with mucormycosis received isavuconazole for a median of 84 days (range, 2–882). By day 42, four patients (11%) had a partial response, 16 (43%) had stable disease, one (3%) had disease progression, three (8%) had missing assessments, and 13 (35%) had died. Day 42 crude all-cause mortality in seven (33%) of 21 primary-treatment isavuconazole cases was similar to 13 (39%) of 33 amphotericin B-treated matched controls (weighted all-cause mortality: 33% vs. 41%; $P = 0.595$).⁴²⁸ Efficacy of isavuconazole has also been demonstrated in a limited number of patients with cryptococcosis and infections caused by dimorphic fungi who were enrolled in the VITAL open-label nonrandomized phase III clinical trial,⁶³³ attesting to the potentially broader clinical usefulness of this agent.

Approval status and dosing. Isavuconazole is approved in both the United States and the European Union for patients 18 years of age and older for treatment of invasive aspergillosis and for treatment of mucormycosis.^{105,193} In the European Union, the indication for treatment of mucormycosis is limited to patients for whom amphotericin B is inappropriate.¹⁹³ The approved dosage for both the intravenous and the oral capsule formulations is a loading dose of 200 mg isavuconazole (corresponding to 372 mg isavuconazonium sulfate) every 8 hours for six doses (48 hours), followed by a maintenance dose of 200 mg of isavuconazole once daily starting 12 to 24 hours after the last loading dose. No dose adjustment is required based on age, gender, or race. In patients with mild, moderate, or severe renal impairment, and in patients with mild or moderate hepatic impairment, no dose adjustment is necessary; for patients with severe hepatic impairment, no data exist and caution is warranted.^{105,193} The pharmacokinetics and safety of isavuconazole in pediatric patients (<18 years) have not been studied yet; formal investigation plans for pediatric development of the compound exist for both the United States and the European Union but remain to be executed.

Echinocandin Lipopeptides

The echinocandins are a distinct class of semisynthetic amphiphilic lipopeptides that are composed of a cyclic hexapeptide core linked to a variably configured lipid side chain. The first compound of this class was cilofungin (LY 121019), an echinocandin B derivative with activity limited to *Candida* spp. However, clinical development was abandoned because of concerns regarding toxicity associated with the intravenous polyethylene glycol formulation vehicle.^{221,251,561} Since the 1990s, a second generation of semisynthetic echinocandins with extended antifungal spectrum against *Candida* and *Aspergillus* spp., excellent safety profiles, and favorable pharmacokinetic characteristics has been developed: anidulafungin (Eraxis and Ecalta), caspofungin (Cancidas and generic forms), and micafungin (Mycamine) (Fig. 240.8). With few exceptions, current data indicate that these agents are not fundamentally different with respect to spectrum, pharmacodynamics, pharmacokinetics, safety, and antifungal efficacy.

Mechanism of action. The echinocandins act by noncompetitive inhibition of the synthesis of $(1 \rightarrow 3)\text{-}\beta\text{-D-glucan}$, a polysaccharide in the cell wall of many pathogenic fungi (Fig. 240.9). Together with chitin, the ropelike glucan fibrils are responsible for the cell wall's strength and shape. They are important in maintaining the osmotic integrity of the fungal cell and play a key role in cell division and cell growth.^{149,150,279} The proposed molecular target of the echinocandins, glucan synthase, is a heteromeric enzyme complex composed of at least one large integral

FIG. 240.8 Structural formulas of echinocandin lipopeptides: anidulafungin, caspofungin, and micafungin.

FIG. 240.9 Schematic of the proposed mechanism of action of echinocandin lipopeptides. Echinocandins inhibit the synthesis of cell wall 1,3-β-glucan at the level of the cell membrane. *FKS* is the proposed catalytic subunit, and *Rho* the proposed regulatory subunit of the glucan synthase complex. (Modified from Kurtz MB, Douglas CM. Lipopeptide inhibitors of fungal glucan synthase. *J Med Vet Mycol.* 1997;35:79-86.)

membrane protein encoded by the *FKS* gene that binds the substrate (UDP-glucose), and one small regulatory subunit, Rho1p, a guanosine diphosphate (GTP)-binding protein; other, as-yet unidentified, components also may be involved.^{369,632} Additional immunomodulatory effects through unmasking of (1→3)-β-D-glucan with proinflammatory host cytokine release have been described and may contribute to in vivo efficacy of the echinocandins.³⁸⁷

Antifungal activity. The echinocandins have potent and broad-spectrum fungicidal in vitro activity against most *Candida* spp., including azole-resistant strains and biofilms, and potent inhibitory activity against *Aspergillus* spp. Their antifungal efficacy against these organisms in vivo has been demonstrated in various animal models. The current

echinocandins have variable activity against dematiaceous and endemic mold and are considered inactive against most Hyalohyphomycetes, Mucorales, *C. neoformans*, and *T. asahii*. All echinocandins have demonstrated preventive and therapeutic activity in animal models of *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) pneumonitis. Preclinical in vitro and in vivo studies consistently have shown no antagonism between echinocandins and other antifungal agents but have shown indifference, additivity, or synergy when tested against *Aspergillus* spp., *C. albicans*, and non-*albicans Candida* spp.^{190,244,248,251,509,667}

Resistance. Whereas the echinocandins show no cross-resistance to amphotericin B, co-resistance to both azoles and echinocandins in clinical isolates of *C. glabrata* may occur^{515,741} and is of concern^{509,598} as

it may be associated with increased all-cause mortality in patients.⁷⁰⁰ Very recently, a mutator phenotype caused by a mismatch repair defect has been described that is prevalent in *C. glabrata* clinical isolates and confers a higher propensity to breakthrough in preclinical experiments, and that may at least partially explain the elevated rates of triazole and multidrug resistance associated with *C. glabrata*.²⁷⁶ Nevertheless, the frequency of resistance to echinocandins in otherwise susceptible fungal yeast species remains overall low.^{509,598} Resistance to echinocandins during the course of therapy also has been reported for *C. krusei*.⁵⁰⁶ Reduced echinocandin susceptibility may occur by three mechanisms: adaptive stress responses, which result in elevated cell wall chitin content and paradoxical growth in vitro at supraminimum inhibitory concentrations that greatly exceed those achieved in plasma (paradoxical effect); acquired *FKS* mutations, which confer reduced glucan synthase sensitivity, elevated MICs and clinical failure; and intrinsic *FKS* mutations. Intrinsic *FKS* mutations are naturally occurring mutations in the *C. parapsilosis* group and *C. guilliermondii* that confer elevated MIC levels but a lower level of reduced glucan synthase sensitivity in contrast to acquired *FKS* mutations. Of note, some *FKS* mutants have been shown to have significantly reduced fitness and virulence, which may contribute to the low incidence of echinocandin resistance reported in large surveillance studies.^{69,369,500,509,598} New, species-specific clinical breakpoints that consider wild-type MICs, epidemiologic cutoff values, and pharmacokinetic and pharmacodynamic relationships have been proposed that are more sensitive to detect emerging resistance associated with *FKS* mutations and better able to predict risk for clinical failure.^{31,509,516}

Relative to *Candida* spp., much less is currently known about echinocandin resistance among *Aspergillus* spp.; however, clinical breakthrough cases have been reported, and resistance has been confirmed in vivo.^{218,305,521}

Pharmacodynamics. The echinocandins demonstrate a species-dependent mode of antifungal activity. Whole-cell in vitro assays reveal fungicidal activity against most *Candida* spp. but not against *Aspergillus* spp.^{51,624} Microscopic examination of drug-exposed *A. fumigatus* shows a dose-dependent formation of microcolonies with progressively truncated, swollen hyphal elements that appear to be cell wall deficient but are able to regain their cell walls on subculture in the absence of drug.^{168,370,482,541} These observations demonstrate differences in functional target sensitivity that are not fully understood. Time-kill studies in *Candida* spp. demonstrated predominantly concentration- and time-dependent fungicidal activity and rate-of-kill at concentrations greater than the MIC for all three compounds.^{187,189,510} In addition, PAFEs between 5 and 12 hours at concentrations above the MIC have been demonstrated.^{188,413}

In persistently neutropenic rabbit models, anidulafungin showed highly predictable concentration-effect relationships in experimental disseminated candidiasis; however, no concentration-effect relationships were observed in experimental pulmonary aspergillosis, despite full exploration of the dosage range.²⁴⁷ Pharmacodynamic studies in murine kidney target models of disseminated candidiasis showed that the AUC/MIC ratio is the pharmacodynamic parameter that predicts efficacy of

the echinocandins.^{21,22,23,398} In a murine model of invasive pulmonary aspergillosis, the C_{max}/MEC ratio appeared to be the parameter most closely associated with efficacy.⁷¹⁷ Pharmacokinetic and pharmacodynamic correlations of all echinocandins have been explored in patients with esophageal and oropharyngeal candidiasis.²⁵⁴ Using large datasets from two phase III clinical trials of micafungin for invasive candidiasis, a significant relationship between the AUC/MIC ratio of micafungin and mycological response was found by population pharmacokinetics and regression analysis; Monte Carlo simulation revealed lower AUC/MIC target for *C. parapsilosis* relative to other *Candida* spp., supporting the concept of species-specific echinocandin susceptibility breakpoints.²¹

Pharmacokinetics. The three currently available echinocandins are available only for intravenous administration. They exhibit dose-proportional plasma pharmacokinetics with a triexponential elimination pattern. Their β half-life is between 10 and 15 hours, thus allowing for once-daily dosing without major accumulation after multiple dosing. All echinocandins are highly ($\geq 95\%$) protein-bound and distribute into all major organ sites, including the brain; however, concentrations in uninfected CSF are low. Within the lung, anidulafungin and micafungin have been shown to predominantly concentrate in alveolar macrophages. The echinocandins are chemically degraded or metabolized by the liver and slowly excreted into urine and feces; only small fractions ($\leq 2\%$) of a dose are excreted into urine in unchanged form (Table 240.13).^{125,137,139,254,668,687} The current echinocandins are not dialyzable, and no adjustment in dose is required for patients with renal insufficiency or renal failure. Similarly, no adjustment in dose is necessary for patients with mild-to-moderate (all) or severe (anidulafungin, micafungin) hepatic failure. Whether the minor differences in individual pharmacokinetic parameters such as AUC, peak plasma levels, volume of distribution, and clearance of the echinocandins are of clinical significance remains to be elucidated.

Adverse effects. At current dosages, anidulafungin, caspofungin, and micafungin generally are well tolerated. Fewer than 10% of patients enrolled in the various randomized comparative clinical trials discontinued echinocandin therapy because of drug-related adverse events.^{148,359,451,539,654,697} Increased liver transaminases, gastrointestinal symptoms, skin rash, and headache probably or definitely associated with echinocandin treatment have been reported to occur at a frequency of less than 5% each. Like other basic polypeptides, the echinocandins have the theoretical potential to cause release of histamine.^{148,359,451,539,654,697} Symptoms such as rash, facial swelling, pruritus, sensation of warmth, and anaphylactic reactions have been reported in isolated cases. Because of transient elevations of hepatic transaminases in interaction studies in healthy volunteers,²⁵⁸ the concomitant use of caspofungin and cyclosporine currently is not recommended; clinical experience, however, indicates that both drugs can be given safely under careful monitoring.^{238,424,640}

Drug interactions. In vitro studies showed that anidulafungin does not significantly inhibit the activities of clinically important human CYP450 isoforms at clinically relevant concentrations and that it is not an inhibitor of P-glycoprotein. Interaction studies demonstrated that no adjustment of dosage of either drug is warranted when anidulafungin

TABLE 240.13 Principal Pharmacokinetic Properties of the Echinocandin Lipopeptides Caspofungin, Anidulafungin, and Micafungin

Properties	Caspofungin	Anidulafungin	Micafungin

is coadministered with cyclosporine, tacrolimus, voriconazole, liposomal amphotericin B, or rifampin.¹⁰⁷

Caspofungin is not a substrate of P-glycoprotein and is a poor substrate and a weak inhibitor of CYP450 enzymes.^{42,732} Clinical studies demonstrated that the pharmacokinetic properties of caspofungin are not altered by itraconazole, amphotericin B, mycophenolate, nelfinavir, or tacrolimus. Caspofungin has no effect on the pharmacokinetics of itraconazole, amphotericin B, or the active metabolite of mycophenolate. Caspofungin can reduce the AUC of tacrolimus by approximately 20%, but it has no effect on cyclosporine levels. Inducers of drug clearance or mixed inducer and inhibitors, namely efavirenz, nelfinavir, nevirapine, phenytoin, rifampin, dexamethasone, and carbamazepine, may reduce caspofungin concentrations, and dose adjustment to a daily dose of 70 mg of caspofungin should be considered.^{104,258,621}

Micafungin is a weak inhibitor of CYP3A *in vitro*, but it is neither a P-glycoprotein substrate nor inhibitor *in vitro*. In clinical studies, micafungin had no effect on mycophenolate mofetil, cyclosporine, tacrolimus, prednisolone, fluconazole, and voriconazole pharmacokinetics, but it increased the AUC of sirolimus, nifedipine, and itraconazole by approximately 20%. Patients receiving sirolimus, nifedipine, or itraconazole in combination with micafungin should be monitored for toxicity of these drugs, and sirolimus, nifedipine, and itraconazole dosage should be reduced if necessary. Amphotericin B, mycophenolate mofetil, cyclosporine, tacrolimus, prednisolone, sirolimus, nifedipine, fluconazole, itraconazole, voriconazole, ritonavir, and rifampin were shown to have no effects on the pharmacokinetics of micafungin.^{108,256}

Caspofungin

Clinical efficacy. The clinical efficacy of caspofungin against *Candida* spp. was demonstrated first in phase II and 3 studies in immunocompromised patients with esophageal candidiasis.^{30,676,677} A multicenter, randomized, double-blind phase III clinical trial investigated the efficacy of caspofungin for primary treatment of invasive *Candida* infections in 224 mostly nonneutropenic patients with D-AmB (0.6–1 mg/kg) as comparator agent. Among patients receiving at least one dose of the study drug, 73% of patients in the caspofungin cohort and 61.7% of patients in the D-AmB cohort had therapeutic success at the end of intravenous therapy. Among patients who received five or more doses, the response rates were 80.7% and 64.9%, respectively. No difference occurred in relapse or survival, but caspofungin was better tolerated.⁴⁵¹ Further large randomized clinical trials in patients with candidemia and other forms of invasive candidiasis showed similar outcomes of the standard dose of caspofungin relative to 100 and 150 mg daily of micafungin⁴⁹⁹ and no general advantage of a high-dose (150 mg/day) caspofungin treatment regimen.⁶⁸ In deep-seated invasive candidiasis, including peritonitis, abdominal abscesses, chronic disseminated candidiasis, and arthritis, caspofungin was effective and safe at regular doses and up to 100 mg daily.¹³⁰

A multicenter phase II salvage trial of caspofungin in 83 patients with definite or probable invasive aspergillosis revealed a complete or

partial response in 45% of patients receiving at least one dose of caspofungin; in patients receiving the drug for more than 7 days, the response rate was 56%.⁴⁰⁶ Rates of complete or partial responses in subsequent exploratory phase II clinical trials for primary treatment of proved or probable invasive aspergillosis appear to correlate with patients' comorbidities and range from 33%⁶⁷⁸ and 42%²⁸⁵ to 54%.¹³³ Caspofungin in combination with a triazole or polyene has been shown to be safe and effective in phase II trials and is an option for salvage therapy of invasive aspergillosis.^{98,255,404}

In a large, randomized, double-blind clinical trial including 1095 patients, caspofungin was as effective as liposomal amphotericin B for empirical antifungal therapy in persistently febrile granulocytopenic patients, but it was better tolerated. The proportion of patients who survived at least 7 days after therapy was greater in the caspofungin group (92.6% vs. 89.2%).⁶⁹⁷ Finally, randomized prospective comparisons suggest that caspofungin may be useful for prophylaxis in high-risk patients with hematologic malignancies.^{103,430}

Approval status and dosing. Caspofungin is licensed in both the United States and Europe in patients 3 months of age or older with candidemia and certain forms of invasive *Candida* infections, as second-line therapy for invasive aspergillosis, and for empirical antifungal therapy in granulocytopenic patients.^{104,191} In the United States, caspofungin also is approved for treatment of esophageal candidiasis (see Tables 240.2, 240.3, and 240.9).¹⁰⁴ The adult dosage regimen is 50 mg daily, with a single 70-mg loading dose on day 1, administered over 1 hour. No dosage adjustment is required in patients with renal insufficiency and mild hepatic insufficiency. In patients with moderate hepatic insufficiency (Child-Pugh category B), a maintenance dose of 35 mg/day is recommended after the loading dose of 70 mg. No recommendations exist for patients with severe hepatic insufficiency (Child-Pugh category C).^{104,192,258}

In children and adolescents 2 to 17 years of age, the pharmacokinetics and safety of caspofungin were investigated using both a weight-based and a body surface-area regimen. Whereas a maintenance dosage of 1 mg/kg per day achieved suboptimal exposure, dosing with 50 mg/m² per day provided similar or slightly higher exposure relative to adults (Table 240.14).⁶⁸² In conjunction with pharmacokinetic data obtained in small children,⁴⁷² the dosage of 50 mg/m² per day (with day 1 dose 70 mg/m² per day and maximum daily dose of 70 mg) has been selected for pediatric patients between 3 months and 17 years of age.^{104,195} This dosing regimen has been confirmed by a population pharmacokinetic study including 124 pediatric patients ages 3 months to 17 years enrolled in four clinical trials.³⁹⁰ In neonates up to 3 months of postnatal age, limited pharmacokinetic data obtained in a small cohort of patients suggest that a dosage of 25 mg/m² per day results in similar bloodstream exposures as 50 mg/m² per day in older patients.^{195,485,567} The experience with anidulafungin and micafungin, however, suggests that higher doses are likely needed to treat CNS infection.

Caspofungin appears to be well tolerated in pediatric patients. In the previously mentioned phase I and II dose-finding studies, none of

TABLE 240.14 Single-Dose Caspofungin Pharmacokinetics in Pediatric vs. Adult Patients^a

Dosage	CHILDREN (2–11 Y)		Adolescents (12–17 y) 50 mg/m ²	Adults 50 mg
	1 mg/kg	50 mg/m ²		
AUC _{0–24 h} (μg/h/mL)	41.5	96.4	77.6	70.6
C1 (μg/mL)	6.59	13.9	7.67	7.67
C24 (μg/mL)	0.45	1.09	1.35	1.35
t _{1/2β} (h)	7.2	7.6	11.7	11.7
Cl (mL/min/m ²)	8.57	7.78	6.07	6.07

^aLeast square means are reported for AUC, C1 (peak plasma concentration [C_{max}]), and C24 (minimum plasma concentration [C_{min}]), and harmonic means for t_{1/2β}. Data were obtained in groups of 6 to 10. Data in pediatric patients were compared with those obtained in 32 adult patients with mucosal candidiasis. In comparison with adult values, a 1-mg/kg dosage does not achieve the target trough concentration of caspofungin of 1 μg/mL and leads to a lower exposure as measured by the AUC_{0–24 h}; the dosage regimen of 50 mg/m² leads to similar or slightly higher trough concentrations and similar or slightly higher exposure (AUC_{0–24 h}).

Modified from Walsh TJ, Adamson PC, Seibel NL, et al. Pharmacokinetics, safety, and tolerability of caspofungin in children and adolescents. *Antimicrob Agents Chemother*. 2005;49:4536–4545.

AUC, Area under the concentration versus time curve from 0 to 24 hours; Cl, clearance; t_{1/2β}, elimination half-life.

the patients developed a serious drug-related adverse event or discontinued because of toxicity.^{472,567,682} In a phase III estimation trial with safety as the primary objective, 82 patients between the ages of 2 and 17 years with persistent fever and neutropenia were randomly assigned to receive caspofungin or liposomal amphotericin B 3 mg/kg daily in a 2:1 ratio. Rates of drug-related adverse events were similar (clinical 48.2% vs. 46.2%; laboratory 10.7% vs. 19.2%); serious drug-related adverse events occurred in 1.8% of caspofungin-treated patients and in 11.5% of amphotericin B-treated patients. Overall success rates were not different.⁴⁰⁷ A prospective phase II trial in 49 patients with invasive *Candida* or *Aspergillus* infections revealed no serious drug-related adverse events and an overall response rate of 73%.⁷³⁸ In the combined analysis of caspofungin safety in all five clinical registration trials involving 171 pediatric patients 1 week to 17 years of age, the most common drug-related adverse events were fever (11.7%), increased alanine transaminase level (6.5%), and rash (4.7%); few events were serious (0.6%) or required treatment discontinuation (1.2%).⁷³⁹ Favorable safety experiences also have been reported in immunocompromised pediatric patients who received the compound for various indications, mostly in combination with other antifungal agents,^{100,166,206,238,452} and in neonates with refractory invasive candidiasis.^{468,484,485} Breakthrough infections with rare fungal pathogens not inherently susceptible to echinocandins have been reported in individual patients and may need to be considered in cases of treatment failure.^{458,734}

Anidulafungin

Clinical efficacy. The clinical efficacy of anidulafungin against *Candida* spp. was demonstrated in phase II or III studies in immunocompromised patients with esophageal candidiasis and candidemia. Anidulafungin had efficacy equivalent to that of fluconazole in esophageal candidiasis in a randomized, double-blind, international multicenter study; success was documented in 242 of 249 evaluable anidulafungin-treated patients (97.2%) and in 252 of 255 fluconazole-treated patients (98.8%). Adverse events leading to discontinuation were reported in 29 anidulafungin-treated patients (10%) versus 23 fluconazole-treated patients (8%).³⁵⁸ In a dose-ranging study in 123 patients with invasive candidiasis randomized to anidulafungin 50, 75, or 100 mg once daily, success rates at end of therapy were 84%, 90%, and 89%, respectively.³⁵⁹ A subsequent randomized, double-blind phase III noninferiority trial compared anidulafungin 100 mg once daily with fluconazole 400 mg once daily in a total of 245 mostly nonneutropenic patients with invasive candidiasis.⁵³⁹ More patients receiving anidulafungin had clinical and microbiologic success at the end of intravenous therapy (75.6% vs. 60.2%); similar superiority was found at the 2- and 6-week follow-up after the end of all therapy (64.6% vs. 49.2% and 55.9% vs. 44.1%, respectively). The rate of death from all causes was 31% in the fluconazole group and 23% in the anidulafungin group ($P = .13$). A randomized double-blind clinical trial comparing open-label voriconazole plus

blinded anidulafungin or blinded placebo for treatment of proved or probable invasive aspergillosis in patients with hematologic malignancies or allogeneic HSCT showed a statistical trend ($P = .07$) favoring the combination therapy with respect to the overall survival at 6 weeks, the primary endpoint of the study.⁴²⁵ In an unscheduled post-hoc analysis of patients diagnosed on the basis of positive galactomannan, which accounted for 78% of the study population, overall survival at 6 weeks was significantly higher in the combination arm. Although the clinical implications of this study are still debated, regulatory approval of this combination has failed.

Approval status and dosing. Anidulafungin is licensed in both the United States and Europe for patients 18 years of age or older for candidemia and certain forms of invasive *Candida* infections in non-neutropenic patients.^{107,192} In the United States, the compound is also licensed for esophageal candidiasis (see Table 240.2).¹⁰⁷ The recommended dose regimen consists of 100 mg (day 1: 200 mg) for invasive candidiasis and 50 mg daily (day 1: 100 mg), for esophageal candidiasis, administered at a rate of 1.1 mg/min or higher. No dosage adjustment is needed in patients with renal impairment, patients undergoing hemodialysis, and patients with hepatic impairment (Child-Pugh classes A, B, and C).^{107,192,549}

A pediatric phase I and II multicenter study of the pharmacokinetics and safety of anidulafungin has been completed in 19 granulocytopenic children with cancer. Patients were divided into two age cohorts (2 to 11 and 12 to 17 years) and were enrolled into sequential groups to receive 0.75 or 1.5 mg/kg per day⁵⁶ (Table 240.15). No drug-related serious adverse events were recorded. Pharmacokinetic parameters were similar across age groups and dosage cohorts and similar relative to adult patients. Following single and multiple daily doses of 0.75 mg/kg and 1.5 mg/kg, plasma concentration data corresponded to those in adults following a daily 50 and 100 mg dose, respectively.⁵⁶ In infants and neonates at risk for invasive candidiasis receiving 1.5 mg/kg per day anidulafungin after a single loading dose of 3 mg/kg, drug exposure levels after multiple doses were similar between neonates and infants and similar to those in children receiving similar weight-based dosing and in adult patients receiving 100 mg/day. No drug-related serious adverse events were observed.¹²⁴ Bridging studies from laboratory animals, however, indicate that a regimen of 3 mg/kg, followed by 1.5 mg/kg per day, is suboptimal for treatment of *Candida* meningoencephalitis and that higher dosages will be required to treat this condition.⁷⁰¹ No further data are available at this point, and the pediatric development program of the compound has not been formally completed.

Micafungin

Clinical efficacy. Micafungin was studied in open-label dose-ranging trials of endoscopically proved esophageal candidiasis in patients with HIV infection.^{513,622} A double-blind comparative study investigating 50, 100, and 150 mg/day versus fluconazole 200 mg/day for HIV-associated esophageal candidiasis showed similar endoscopic cure rates and safety

Data from Benjamin DK Jr, Driscoll T, Seibel NL, et al. Safety and pharmacokinetics of intravenous anidulafungin in children with neutropenia at high risk for invasive fungal infections. *Antimicrob Agents Chemother.* 2006;50:632–638; and Vasquez JA, Sobel JD: Anidulafungin: a novel echinocandin. *Clin Infect Dis.* 2006;43:215–222.

profiles for micafungin at doses of 100 and 150 mg/day and fluconazole.¹⁴⁸ A further randomized, double-blind comparative trial in 523 patients 16 years of age and older with esophageal candidiasis investigated micafungin 150 mg/day versus fluconazole 200 mg/day.¹⁴⁷ For the primary endpoint of endoscopic cure, treatment difference was 0.3% (micafungin, 87.7%; fluconazole, 88.0%). A large randomized, double-blind noninferiority trial compared micafungin 100 mg once daily and liposomal amphotericin B 3 mg/kg once daily for first-line therapy of candidemia and other forms of invasive candidiasis in a total of 531 adult patients. The overall success rate in both treatment arms was similar (89.6% vs. 89.5%). No differences in survival were noted. Fewer severe treatment-related adverse events and adverse events that led to treatment discontinuation were observed in the micafungin arm.^{371,557} In a second large, phase III, randomized clinical trial of a total of 595 patients with candidemia and other forms of invasive candidiasis, micafungin at 100 mg/day, micafungin at 150 mg/day, and caspofungin at 50 mg/day (with day 1 dose 70 mg) were equivalent in terms of efficacy, adverse events, and mortality.^{178,499} A multinational, noncomparative open-label trial investigated micafungin for proved and probable invasive aspergillosis alone or in combination with another antifungal agent. A favorable response rate at the end of therapy was seen in 35.6% (80 of 225) of patients. Of those treated with only micafungin, favorable responses were seen in 6 of 12 (50%) of the primary and 9 of 22 (40.9%) of the salvage therapy group, with corresponding numbers in the combination treatment groups of 5 of 17 (29.4%) and 60 of 174 (34.5%) of the primary and salvage treatment groups, respectively.¹⁵¹ Finally, micafungin 50 mg/day (<50 kg, 1 mg/kg) versus fluconazole 400 mg/day (<50 kg, 8 mg/kg) was investigated for prevention of invasive fungal infections in 882 patients undergoing HSCT. Prophylaxis was given from the start of the conditioning regimen until 5 days after engraftment. The overall success rate was significantly higher for patients randomized to receive micafungin (80.0% vs. 73.5%; $P = .03$). Drug-related adverse events were comparable.⁶⁵⁴

Approval status and dosing. In the United States, micafungin is licensed in adults and pediatric patients at least 4 months of age for prevention of *Candida* infections in patients undergoing HSCT, for treatment of candidemia and defined forms of invasive candidiasis, and for treatment of esophageal candidiasis (see Table 240.2).¹⁰⁸ In Europe, the compound is licensed for use in neonates, children, and adults for treatment of invasive candidiasis and as prophylaxis of *Candida* infections in patients with allogeneic HSCT and those with prolonged neutropenia; it is also licensed for treatment of esophageal candidiasis in individuals 16 years of age and older.¹⁹¹ The recommended dosage is 100 mg/day for invasive candidiasis (US: ≤30 kg, 2 mg/kg; EU: ≤40 kg, 2 mg/kg), 150 mg/day for esophageal candidiasis (US: ≤340 kg, 3 mg/kg, >30 kg 2.5 mg/kg [maximum 150 mg]; EU: ≤40 kg, 3 mg/kg), and 50 mg/day (≤40 kg,

1 mg/kg) for the preventive indication. According to the European label, for invasive candidiasis, the dose may be increased to 200 mg/day in patients weighing more than 40 kg or 4 mg/kg per day in patients weighing 40 kg or less if the patient's response is inadequate.¹⁹⁴ The approved doses for children and neonates less than 4 months of age is 2 mg/kg and per day for prophylaxis of invasive candidiasis and 4 to 10 mg/kg and per day for treatment of invasive candidiasis. The SPC states that in this population, 4 mg/kg approximates drug exposures achieved in adults receiving 100 mg/day and that, if infection of the CNS is suspected, a higher dosage (e.g., 10 mg/kg) should be used. It also states that the safety and efficacy of doses of 4 and 10 mg/kg for the treatment of invasive candidiasis with CNS involvement has not been adequately established in controlled clinical studies.¹⁹⁵ Renal dysfunction, dialysis, or hepatic dysfunction does not alter the pharmacokinetics of micafungin and accordingly, no dose adjustments are required.^{108,278}

The pharmacokinetics and safety of micafungin have been studied in 70 febrile granulocytopenic children 2 to 17 years of age. Micafungin was well tolerated at dosages of 0.5 to 3 mg/kg per day; pharmacokinetics were linear and similar to those observed in adults (Table 240.16).⁵⁹⁰ Further pharmacokinetic studies in different populations of children of the same age range dosed between 1 and 4.5 mg/kg per day resulted in similar observations.^{11,55,651} Population-based pharmacokinetic modeling of the data of the first dose-ranging study²⁹⁹ and of pharmacokinetic data of 229 patients ages between 4 months and less than 17 years from four phase I and two phase III clinical trials²⁹⁷ that used AUC₂₄ target ranges of adults confirmed that dose regimens of 1, 2, and 3 mg/kg per day micafungin are appropriate for the prevention of invasive candidiasis, the treatment of invasive candidiasis, and the treatment of esophageal candidiasis, and that cutoffs of 40 or 50 kg for weight-based dosing resulted in heavier children being appropriately dosed. Of note, in the setting of prophylaxis, alternate dosing of micafungin (3 mg/kg) every other day provides drug exposure similar to standard dosing of 1 mg/kg given daily,⁴³⁴ and alternate dosing may provide an alternative for antifungal prophylaxis in high-risk patients.^{76,434}

The pharmacokinetics in neonates were explored in a phase I single-dose, multicenter, open-label, sequential-dose trial of micafungin 0.75 mg/kg, 1.5 mg/kg, and 3 mg/kg in 18 premature infants weighing more than 1000 g. On average, half-life was shorter and clearance more rapid in contrast to older children and adults.²⁸⁶ Population pharmacokinetics modeling of the neonatal pharmacokinetics data and Monte Carlo simulation suggest that a larger neonatal dose is required to produce drug exposure comparable to those predicted on the basis of weight in children and adults; additional population pharmacokinetics based on open-label pharmacokinetics studies in which doses up to 15 mg/kg per day were safely administered support a target dose of

Modified from Seibel NL, Schwartz C, Arrieta A, et al. Safety, tolerability, and pharmacokinetics of micafungin (FK463) in febrile neutropenic pediatric patients. *Antimicrob Agents Chemother*. 2005;49:3317–3324; and Groll AH, Stergiopoulou T, Roilides E, et al. Micafungin: pharmacology, experimental therapeutics and clinical applications. *Expert Opin Investig Drugs*. 2005;14:489–509.

10 mg/kg for neonates, particularly in view of the substantial risk for secondary brain involvement.^{58,298,300,608} Although the treatment results in the pivotal candidemia study showed no signal for decreased efficacy at dosages between 2 and 4 mg/kg in this population,⁵³⁴ a dose of at least 4 mg/kg in neonates with invasive candidiasis and a dose of 10 mg/kg in the case of CNS involvement is advocated.

A noncomparative phase II study investigated the activity of micafungin in combination with other agents (primarily liposomal amphotericin B) in 58 pediatric patients with mostly refractory invasive aspergillosis. The mean daily dose was 2.0 ± 1.2 mg/kg per day, and the mean duration of dosing was 67 ± 85 days. Overall response was 26 of 58 (45%). Thirteen patients (22%) discontinued micafungin, primarily because of a progression of underlying disease or invasive aspergillosis.²⁰² The comparative safety of micafungin was investigated in the pediatric subpopulation of a double-blind, phase III trial in patients with invasive candidiasis or candidemia. Patients were randomized to receive intravenous micafungin 2 mg/kg per day or liposomal amphotericin B 3 mg/kg per day for a minimum of 14 days. There was no difference in the success rates (69.2% vs. 74.1%). The incidence of serious adverse events (3.8% vs. 9.3%) and the rate of patients discontinuing therapy because of an adverse event (3.8% vs. 16.7%) were lower in patients treated with micafungin.⁵³⁴ In a pooled analysis of adverse events data from six clinical trials that included close to 300 patients, 26.7% of patients had a treatment-related adverse event and 2.4% had a treatment-related adverse event that led to treatment discontinuation. No trends were seen with respect to dose or duration of treatment, and the types and rates of events were similar to those observed in adults.^{34,35} Data from a large uncontrolled study of micafungin 1 mg/kg per day as prophylaxis during the neutropenic phase post allogeneic HSCT conducted in Korea⁵⁰² and of two large postapproval studies conducted by the manufacturer in Japan in the prophylactic and therapeutic setting^{344,345} that enrolled a total of close to 600 pediatric patients of all age groups further attest to the safety of the compound. Last, in a systematic review of safety data of nine clinical trials involving 116 premature and nonpremature infants less than 2 years of age, treatment-related adverse events were recorded in 23% of patients; relative to low-birth-weight infants, more extremely low-birth-weight (15%) and very-low-birth-weight (40%) infants experienced treatment-related adverse events, but there was no relation to micafungin dose or duration.⁴¹⁷

In Europe, the Summary of Product Characteristics for micafungin recommends careful monitoring of liver function and early discontinuation in the presence of significant and persistent elevation of alanine transaminase and aspartate transaminase values. It also recommends that micafungin treatment be conducted on a careful risk-benefit assessment, particularly in patients with liver diseases or concomitant hepatotoxic-genotoxic therapies.¹⁹¹ This recommendation is based on preclinical data from a high-dose, long-term exposure model in rats treated with micafungin for either 3 or 6 months (equivalent to 12.5% or 25% of the total life span of the rat, respectively). The observed development of foci of altered hepatocytes and liver tumors in this species was dependent on both dose and duration of micafungin treatment. The human relevance of this finding is presently not known.

Agents for Systemic Treatment of Mycoses of the Skin and Its Appendages

Griseofulvin

Griseofulvin (Fig. 240.10) was isolated originally in 1939 as a natural product of *Penicillium griseofulvum*.⁴⁹³ However, only in the late 1950s

was it reported to be effective as an antifungal agent.²²⁰ Griseofulvin has been used since extensively for the systemic treatment of superficial dermatophyte infections in both adults and children.

Mechanism of action. Griseofulvin interferes with fungal microtubule formation. It disrupts the cell's mitotic spindle formation and thus arrests the metaphase of cell division.²⁶² Several additional mechanisms of action have been proposed, including inhibition of nucleic acid synthesis, interference with the synthesis of cell wall chitin, and anti-inflammatory properties.²⁶⁷ Griseofulvin is deposited in keratin precursor cells and produces an unfavorable environment for fungal invasion; infected skin, hair, and nails are replaced with tissue not infected by the dermatophyte.

Antifungal activity. As evident from its mechanism of action, griseofulvin is a fungistatic compound. It is active against *Trichophyton*, *Microsporon*, and *Epidermophyton* spp. The drug has no activity against yeastlike organisms such as *Candida* spp., *Pityrosporum* spp., and *C. neoformans*. It also is inactive against opportunistic hyaline and dematiaceous molds and the dimorphic (endemic) molds.^{199,208}

Pharmacokinetics. Griseofulvin is commercially available for oral administration only as generic griseofulvin microsize and griseofulvin ultramicrosize in suspension and tablet forms. Griseofulvin is weakly water soluble and poorly absorbed from the gastrointestinal tract. In contrast to nonmicrocrystalline drug preparations, microsize and ultramicrosize formulations display enhanced absorption, particularly when polyethylene glycol is used as dispersion carrier in the ultramicrosize formulations. Oral bioavailability of the microsize formulation is variable and ranges from 25% to 70%; ultramicrosize griseofulvin, in contrast, is almost completely absorbed.^{73,267}

After oral administration, C_{max} occurs approximately 4 hours after dosing. Griseofulvin distributes to keratin precursor cells and is concentrated in skin, hair, nails, liver, adipose tissue, and skeletal muscles. In skin, over time, a concentration gradient is established, with the highest concentrations found in the outermost stratum corneum.^{185,594} Non-protein-bound drug is carried in the extracellular fluid, in sweat, and through transepidermal fluid loss; in addition, reversible protein binding and high lipid solubility cause griseofulvin to partition into the stratum corneum, where its concentrations exceed that of serum. Within 48 to 72 hours after discontinuation of the drug, plasma concentrations of griseofulvin are markedly reduced, and the compound no longer is detectable in the stratum corneum.^{73,267}

Griseofulvin is oxidatively demethylated and conjugated with glucuronic acid primarily in the liver; its major metabolite, 6-desmethylgriseofulvin, is microbiologically inactive.³⁹² The elimination of the compound from plasma is bi-exponential, with a terminal elimination half-life of 9 to 21 hours.⁵⁵⁵ Approximately one third of a single dose of microsize griseofulvin is excreted in feces, and 50% is excreted in urine within 5 days. In urine, the drug is excreted mainly as free and glucuronized 6-desmethylgriseofulvin. Unchanged drug in the urine accounts for less than 1% of the dose.^{391,392}

Separate pharmacokinetic data for pediatric patients have not been published; however, the compound is approved for children older than 2 years of age. The recommended pediatric dosage of microsize griseofulvin is 10 to 20 mg/kg per day, with a maximum of 1 g, administered in two divided doses; the recommended pediatric dosage of ultramicrosize griseofulvin is 5 to 10 mg/kg per day (maximum, 750 mg), also given in two divided doses.^{182,210}

Adverse effects. Griseofulvin has an acceptable safety profile. More common adverse effects include headaches and a variety of gastrointestinal symptoms. Griseofulvin can cause photosensitivity and exacerbate lupus and porphyria. Cases of erythema multiforme-like reactions, toxic epidermal necrolysis, and a reaction resembling serum sickness have been reported. Proteinuria, nephrosis, hepatotoxicity, leukopenia, menstrual irregularities, and mental confusion have been reported rarely in association with griseofulvin therapy. Griseofulvin has been noted to produce estrogen-like effects in children and reversible diminution of hearing.^{73,208,267} Griseofulvin is contraindicated in patients with porphyria or hepatocellular failure. The compound has been shown to be teratogenic in animals and should not be administered to pregnant women. Griseofulvin also has mutagenic and carcinogenic potential; the significance of these observations for humans, however, is unclear.^{210,208}

Griseofulvin

FIG. 240.10 Structural formula of griseofulvin.

Drug interactions. Griseofulvin has been noted to enhance the clearance of oral contraceptives, cyclosporine, theophylline, aspirin, and warfarin. Concurrent use of phenobarbital may lead to decreased levels of griseofulvin. Finally, concurrent ingestion of alcohol may lead to a disulfiram-like reaction.^{210,208}

Indications. Griseofulvin remains an option for the treatment of tinea capitis, particularly when caused by *Microsporon*,^{115,184,200} and for refractory tinea corporis (see Table 240.8).^{275,592} For tinea capitis, 6 to 8 weeks of treatment usually are required.^{182,306} The usual duration of therapy for refractory tinea corporis is 4 weeks.^{182,210} Nail infections, which are increasingly observed in the pediatric population,²²² usually fail to respond to therapy with griseofulvin and are better treated with itraconazole or terbinafine.²⁶⁵ Because griseofulvin is not effective against other fungal infections (see Table 240.9), the infecting organism always should be identified as a dermatophyte before therapy is initiated. In vitro resistance of dermatophytes to griseofulvin has been reported and may be the cause of therapeutic failure.³⁸

Terbinafine

The allylamine terbinafine (Fig. 240.11) (Lamisil; and generic forms) is a synthetic antifungal agent that is useful for topical and systemic (oral tablets and suspension) treatment of superficial infections of the skin and its appendages by dermatophytes and yeasts, as well as possibly for treatment of cutaneous sporotrichosis. Terbinafine acts by inhibiting the biosynthesis of fungal ergosterol at the level of squalene epoxidase (see Fig. 240.8), thus leading to depletion of ergosterol and accumulation of toxic squalenes in the fungal cell membrane.⁴⁵

Antifungal activity. Terbinafine has exceptionally potent and fungicidal in vitro activity against dermatophytes.³⁰⁰ It also is highly active against *Aspergillus* spp., certain *Hyalohyphomycetes*, dematiaceous and dimorphic fungi, and *P. jiroveci*. Its in vitro activity against yeasts appears more variable.^{217,251,319,560} Comparative in vitro studies have indicated that terbinafine may be more active against *Aspergillus* spp. than itraconazole⁵⁹³ or amphotericin B,⁵⁷⁹ more active than itraconazole against *S. schenckii*,³⁴⁷ and less active or comparably active relative to the azoles against yeasts.³⁹³

Terbinafine

FIG. 240.11 Structural formula of terbinafine.

Synergy with triazoles against *C. albicans*,^{204,706} *C. glabrata*,⁴⁸ *C. neoformans*,²⁰⁴ *A. fumigatus*,^{82,461} non-*Aspergillus* hyalohyphomycetes,^{435,436,489,560} and Mucorales²³¹ has been reported. Although more variable, synergy with amphotericin B also has been demonstrated for filamentous and yeast like fungi.⁵⁶⁰ Unfortunately, because of the limited systemic distribution of terbinafine, this in vitro activity and synergy has limited in vivo efficacy in treatment of deeply invasive fungal infections. Terbinafine resistance in clinical dermatophyte isolates is a rare occurrence³²⁰; only two cases have been documented, in which the resistance mechanism was identified as a single amino acid substitution in squalene epoxidase.⁴⁹⁰

Pharmacokinetics. The pharmacokinetic properties of terbinafine in adults are well characterized.⁴⁵ Independent of food, oral bioavailability is 70% to 80%. Over the adult dosage range of 125 to 750 mg once daily, terbinafine displays linear plasma pharmacokinetics. C_{max} of 0.5 to 2.7 g/L is measured within 2 hours,^{316,353,354} and steady state is reached after 10 to 14 days after only twofold accumulation.⁴⁵ As a lipophilic drug, terbinafine is strongly bound to plasma proteins. The compound is distributed extensively to tissues and accumulates throughout adipose tissues, dermis, epidermis, and nail. It exhibits a triphasic distribution pattern in plasma, with a terminal half-life up to 3 weeks; microbiologically active concentrations can be measured in plasma for weeks to months after the last dose, a finding consistent with a slow redistribution from peripheral tissue and adipose tissue sites.^{45,354,471} Terbinafine undergoes extensive and complex hepatic biotransformation that involves at least seven CYP450 enzymes⁶⁷⁴; 15 mycologically inactive metabolites have been identified, mainly in urine.³⁵⁴ Studies employing radiolabeled drug demonstrated that urinary excretion accounts for more than 70% and fecal elimination for 10% of radioactivity; the extent of enterohepatic recycling is unknown.^{308,310} As a consequence of the compound's extensive hepatic metabolism and urinary excretion, caution is warranted in treating patients with severe hepatic and renal impairment (creatinine clearance ≤ 50 mL/min).⁴⁵

The pharmacokinetic properties of terbinafine and five known major metabolites in plasma and urine were investigated after single and repeated oral administration of 125 mg/day to 12 pediatric patients for up to 56 days (mean age, 8 years; age range, 5 to 11 years; weight range, 17–34 kg) (Table 240.17).³¹⁰ No differences were found regarding the metabolism of terbinafine relative to healthy adults.³⁰⁹ Steady state was reached at least on day 21, and no further accumulation occurred between days 21 and 56.^{308,475} Comparison of the kinetic parameters of terbinafine after single administration of 125 mg showed comparable C_{max} and T_{max} (time until occurrence of C_{max}) values and a 40% higher AUC; when dose was calculated as milligrams per kilogram or milligrams per square meter, children showed a lower AUC (range, 29–45%) in contrast to that in adults, a finding indicating a higher, weight-normalized volume of distribution into lipophilic tissue. Children had shorter β -phase elimination half-lives, but the γ -phase terminal half-life determined after multiple dosing during washout was similar to that in adults. Thus, in children weighing 17 to 34 kg, a dose of 125 mg terbinafine

TABLE 240.17 Pharmacokinetic Parameters of Terbinafine in Children After a Single Dose of 125 mg Compared With Similar Parameters in Healthy Adults^a

Parameters	Children With Tinea Capitis (n = 12)	Healthy Adults (n = 16)	Statistical Comparison
Age (y)	8 ± 2	26 ± 4	—
Weight (kg)	26 ± 5	64 ± 6	—
C_{max} (µg/mL)	0.706 ± 0.277	0.565 ± 0.329	NS
T_{max} (h)	2.1 ± 1.1	5 ± 0.7	NS
$AUC_{0-\infty}$ (µg/mL/h)	2.967 ± 0.965	2.135 ± 1.131	$P < .05$
$t_{1/2\beta}$ (h)	14.7 ± 4.3	27 ± 12	$P < .001$

^aMean values ± SD.
 $AUC_{0-\infty}$, Area under the concentration versus time curve from zero to infinity; C_{max} , peak plasma concentration; NS, not significant; $t_{1/2\beta}$, elimination half-life; T_{max} , time until occurrence of peak plasma concentration.
Modified from Jones TC. Overview of the use of terbinafine (Lamisil) in children. *Br J Dermatol.* 1995;132:683–689.

yields pharmacokinetic properties similar to those in adults without drug accumulation, and dose calculation of milligrams per kilogram or milligrams per square meter would lead to lower drug levels than those recorded in adults.^{2,308,324,475} Exploration of lower doses (62.5 mg/day) in eight children weighing 19 to 35 kg revealed an approximate reduction in trough level of 50%, indicating linearity of plasma pharmacokinetics in children.³²⁴ Based on the experience with dosages of 10 mg/kg and less in adults and the described pharmacokinetic profile in children, a dose of 250 mg/day has been proposed for children weighing more than 40 kg, a dose of 125 mg/day for children weighing 20 to 40 kg, and 62.5 mg/day for children weighing less than 20 kg.³²⁴

Adverse effects. In adults, terbinafine usually is well tolerated at doses of up to 500 mg/day, and it has a relatively low incidence of adverse effects. Primary adverse effects include gastrointestinal upsets, headache, and skin reactions in 2% to 7% of patients. Terbinafine can cause hepatitis and liver failure. Potentially severe hepatotoxicity is estimated to occur in one in 120,000 patients, and asymptomatic rises in liver enzyme activities are likely to occur at a frequency of one in 200. As a consequence, the drug should not be administered in patients with an underlying liver problem, and liver function tests results should be obtained before terbinafine is prescribed. Less common but relevant adverse effects include mostly reversible loss of taste and/or smell; severe skin eruptions, including generalized erythematous pustulosis and drug-induced lupus erythematosus; Stevens-Johnson syndrome; blood dyscrasias; visual disturbances; and depressive symptoms.⁵ No evidence indicates that these idiosyncratic effects are increasing in incidence with the increasing use of terbinafine.⁴⁹² Terbinafine has not been shown to be carcinogenic or mutagenic; its use is not recommended during pregnancy or in nursing mothers.

Several clinical studies have documented the safety of terbinafine in pediatric patients.^{90,97,209,211,263,324,355,394,475,600} Terbinafine, administered for a median duration of 4 weeks (range, 1 to 28 weeks) was safe in children between 2 and 17 years of age who received the drug for various dermatophyte and yeast infections of the skin: of a total of 196 patients enrolled in six studies, 22 adverse events were observed in 15 patients. Adverse events probably associated with the use of terbinafine occurred in six of these patients (3%), but in none of these patients did terbinafine therapy have to be discontinued.³²⁶ Terbinafine was similarly well tolerated in two double-blind, randomized trials in children with tinea capitis.^{184,209,394}

Drug interactions. Multiple CYP450 enzymes are involved in the metabolism of terbinafine. However, with the possible exception of CYP2D6 substrates, in vitro studies revealed little or no effect on the metabolism of many characteristic CYP substrates.⁶⁷⁴ Inhibition of CYP2D6-mediated metabolism may be relevant with the concomitant use of tricyclic antidepressants, β blockers, selective serotonin reuptake inhibitors, and type B monoamine oxidase inhibitors.

In clinical interaction studies, no pharmacokinetic or pharmacodynamic interactions were observed with the concomitant administration of terfenadine,⁵⁵¹ midazolam,¹⁰ and alfentanil.⁵⁶⁴ Terbinafine can (1) reduce the clearance of theophylline⁶⁴¹; (2) increase levels of nortryptiline,⁶⁵⁸ amitriptyline,¹⁰¹ desipramine,⁴⁰² imipramine,⁶²⁹ paroxetine⁷³³ and dextromethorphan⁴; (3) increase or reduce warfarin exposure^{266,703}; and (4) reduce the trough cyclosporine concentration in patients with transplants.³⁹⁵ Clearance of terbinafine may be decreased by cimetidine and increased by rifampin.²⁵¹

Clinical indications. Terbinafine is approved by the FDA in patients older than 18 years of age for the treatment of onychomycosis of toenails and fingernails caused by dermatophytes. It may be indicated for treatment of other superficial infections of the skin and its appendages caused by dermatophytes,^{5,45,210} for cutaneous and lymphocutaneous sporotrichosis,^{113,308} for subcutaneous phaeoerythromycosis^{79,537} (see Tables 240.4 and 240.8), and for seborrheic dermatitis.⁶⁶⁹ Recommended durations of treatment for tinea capitis, tinea corporis, and tinea pedis, fingernail onychomycosis, and toenail onychomycosis in adults are 4, 2, 6, and 12 weeks, respectively.^{324,592}

Several studies have explored the clinical efficacy of terbinafine in children and adolescents.^{90,97,211,324,355,394,475,600} The overall mycological and clinical efficacy for 152 children ages 2 to 17 years with various dermatophyte and yeast infections of the skin exceeded 95%.³²⁴ In a

prospective, randomized clinical trial in 210 children comparing treatment with 4 weeks of terbinafine versus 8 weeks of griseofulvin for *Trichophyton* tinea capitis, both regimens showed overall similar efficacy.²¹¹ In a subsequent study of the duration of treatment in 176 patients, both 2 and 4 weeks of treatment were clinically superior to a 1-week regimen and had similar treatment efficacy, a finding suggesting that a 2-week course may be sufficient for patients with *Trichophyton* tinea capitis.²⁰⁹ A similar study performed in 134 patients with *Microsporon* tinea capitis investigating 6, 8, 10, or 12 weeks of therapy demonstrated that 6 weeks of therapy were equivalent to griseofulvin.³⁹⁴ Meta-analyses of terbinafine for the treatment of tinea capitis showed safety and efficacy similar to that of griseofulvin and itraconazole for infections caused by *Trichophyton* spp.,^{115,200} superior efficacy to griseofulvin in children with *T. tonsurans* infection, but less clinical efficacy than griseofulvin in children with *Microsporon* infections.¹¹⁵ A systematic review of 26 studies published between 1976 and 2011 on systemic treatment of onychomycosis in children found efficacy and safety profiles of terbinafine, itraconazole, griseofulvin, and fluconazole similar to those previously reported for adults.²⁶⁵

The broad-spectrum fungicidal in vitro activity, systemic availability, and lack of significant side effects suggested potential usefulness of terbinafine against deep-seated fungal infections. However, terbinafine was ineffective in animal models of pulmonary and disseminated aspergillosis,^{339,580} systemic sporotrichosis,³²⁷ cerebral phaeoerythromycosis, disseminated candidiasis, and pulmonary cryptococcosis,⁵⁵⁹ findings explained by nonsaturable protein-binding kinetics.⁵⁸⁰ Against experimental pulmonary pneumocystosis, terbinafine was active in some,^{127,128} but not all,⁶⁹⁹ models.

TOPICAL ANTIFUNGAL AGENTS

Apart from fungal keratitis, the use of topical antifungal agents is confined to superficial infections of the skin and mucosal surfaces. The decision to treat superficial infections of the skin and mucosal surfaces with a topical or systemic agent depends mainly on the site and extent of the infection. Immunocompromised children, however, usually require systemic therapies, as do patients with tinea capitis and onychomycosis (see Tables 240.8 and 240.9).^{182,275}

Topical Therapeutics for Superficial Skin Infections

Dermatophytosis is caused by the filamentous fungi *Microsporon* spp., *Trichophyton* spp., and *Epidermophyton floccosum*. Many different agents and formulations are available for topical treatment of dermatophytic skin infections (i.e., tinea corporis, facialis, or pedis), including allylamines and azoles. Agents for treatment of *Candida* dermatitis and tinea (pityriasis) versicolor (caused by *Malassezia furfur* or *Malassezia pachydermatis*) include various topical azoles and topical polyenes. Most topical agents are applied twice daily well beyond the clinical resolution of the infection. A detailed review of the pharmacologic properties of these topical drugs and of the treatment of cutaneous mycoses is beyond the scope of this chapter and can be found elsewhere.^{182,210,275,306}

Topical Therapeutics for Mucosal Candidiasis

Agents for the topical treatment of vulvovaginal candidiasis include a large variety of antifungal azoles and the polyene nystatin.^{60,611,610} Azole agents may be absorbed to a minor extent and potentially can interfere with the metabolism of concomitant drugs. For example, potentiation of the anticoagulatory effects of acenocoumarol was noted after vaginal administration of miconazole capsules to two postmenopausal patients³⁷² and after oral administration of miconazole gel in three elderly patients with oral candidiasis.⁴⁸⁸

Antifungal azoles such as clotrimazole and miconazole and antifungal polyenes such as amphotericin B and nystatin are effective in the treatment of oropharyngeal candidiasis. Many clinical trials evaluated the usefulness of these agents for prevention of fungal infections in immunocompromised patients with cancer or HSCT. Although most agents have documented efficacy in the prevention of oropharyngeal candidiasis, they are not effective in preventing invasive mycoses and in improving infection-related and overall mortality in this setting.^{180,253,302,397,637,652}

FUTURE DIRECTIONS

Pediatric age groups display important differences in host biology, predisposing conditions, epidemiology, and presentation of fungal infections relative to the adult population. Since the late 1990s, major advances have been made in the field of medical mycology. Most importantly, an array of new antifungal agents has entered the clinical arena. Although the final pediatric approval of some of these agents remains to be established, the development of pediatric therapies has moved forward in an exemplary manner. Invasive fungal infections will remain important causes of morbidity and mortality in immunocompromised pediatric patients. The availability of alternative therapeutic options is an important advance; at the same time, however, antifungal therapy has become increasingly complex, and clinical surveys indicate a substantial need for improvement in antifungal prescribing.^{382,386} In addition to information on prior antifungal therapies, microbiologic data, existing comorbidities, and concurrent medications, guidance through the available antifungal armamentarium and pivotal clinical trials through pediatric specific recommendations^{239,296} is needed more than ever in the management of the individual patient.
